As I shall point out shortly, there is danger, considerably more danger, of placing too much emphasis and reliance upon negative reactions as an index of cure. As shown above, a single negative reaction and even a series of two or three over a period of three or four months may not mean permanent freedom from relapse. There should always be a minimum amount of treatment regardless of negative reactions, because spirochetes may be so reduced in numbers, activity or both to give temporary periods when "reagin" production is not sufficient for yielding positive reactions. All the more reason, therefore, for properly evaluating the positive reaction and accepting it as an evidence of continued spirochetic infection, provided always that it is based upon a technically acceptable method and that the positive reactions persist after suitable periods of rest from specific medication. I repeat as my firm conviction, based upon both clinical and serological experience, that the complement-fixation reaction is a most valuable guide in the treatment of syphilis; that it is usually the last sign of the disease to disappear and the first to reappear if our therapeutic efforts have failed in completely eradicating *Spirochæta pallida* from the tissues and that the goal of our efforts should be to secure persistently negative reactions over years of time with the most specifically sensitive complement-fixation methods available even though this means continuing treatment after the obvious lesions have long since disappeared and even though in some few cases we may be compelled to abandon this goal because of factors preventing or rendering inadvisable the amount of treatment required for attaining such results.

Complement-fixation Reaction as an Index of Relapse in Syphilis.—As just stated, when the complement-fixation reaction is conducted by a specifically sensitive method, it is usually the last sign of syphilis to disappear under treatment; with relatively less sensitive methods, the reactions may be negative in the presence of active lesions and this may occur in rare instances even with sensitive methods, although in such instances errors in technic and especially the use of defective antigen are to be suspected.

Likewise, after the apparent cure of syphilis with a series of negative reactions, the positive reaction is usually the first sign of relapse, the first indication that the spirochetes are still in the tissues and that complete cure has not been effected. Of course, the percentage of relapses depends upon the thoroughness of preceding treatment and figures published by various investigators are of little interest and importance, because methods of treatment have varied so greatly; but percentages, and especially such valuable investigations as those of Craig, have firmly established the principle that recurring positive Wassermann reactions are acceptable as signs of incomplete cure and the resumption of renewed spirochetic activity. As shown by

Craig, relapsing positive reactions bear a relation not only to the stage of the disease but to the kind and thoroughness of treatment.

Just how long a period of time with consistently negative reactions is required before we may feel reasonably sure that relapses will not occur, is a matter largely of personal opinion and will be shortly discussed; but here I hope to make clear that a recurring positive complement-fixation reaction with a technically acceptable method is frequently, and indeed usually, the first sign of relapse and may be present weeks and months before clinical evidences of relapse are apparent. If space permitted, case after case could be here recorded in support of these assertions, but they are so common that doubtless most physicians treating syphilis are sufficiently familiar with them. But we should not wait for clinical evidences before instituting treatment, as this means the loss of much valuable time and the necessity for treating a heavier infection. It is scarcely necessary to repeat again that the method employed should be as sensitive as consistent with specificity and that the tests should be made at intervals over a period of several years for the purpose of detecting the very first evidences of incomplete cure and renewed spirochetic activity.

Complement-fixation Reaction as an Index of the Cure of Syphilis.—And now we arrive at the important question regarding the reliability of persistently negative complement-fixation reactions as evidence of the cure of syphilis.

In the first place, let us get rid of the single negative reaction. Such is absolutely no evidence at all of cure. Frequently and indeed usually, the first negative reaction is followed later by positive reactions. The wise physician will never cease specific medication in syphilis on the evidence of the first negative reaction, even though this occur a year or more after all obvious clinical evidences of the disease have disappeared. The first negative reaction should always be followed by further treatment, but this need not be as intensive as previously employed since a lighter infection remains, as I shall discuss in more detail in later chapters devoted to treatment.

And I hope that I will not tire my readers with again advising the employment of a test yielding reactions as sensitive as possible with practical specificity for syphilis. To be of any value at all the method must yield reactions capable of detecting the first evidences of recurring or relapsing syphilitic infection before such becomes clinically apparent by the production of lesions.

It is commonly stated that a series of negative blood reactions should be observed over a period of not less than a year and preferably two years with a total absence of all clinical signs and symptoms of syphilis, together with a normal spinal fluid, before one may safely express an opinion that complete cure has been obtained. Whether or not this is true I am not able to state. It seems to me that we must suspend judgment and opinion for a sufficient period of time to permit time to tell the story, and time alone can properly evaluate for us our present-day methods and opinions. But I believe that, when these requirements are fulfilled, the results do indicate complete cure, in many cases at least, and especially those cases of syphilis in which active treatment is instituted during the primary and not later than the secondary stages. The longer the disease has been present before treatment is begun the more conservative we should be in accepting a series of negative complement-fixation reactions as a criterion of cure. For example, in cases of primary syphilis I believe that a series of consistently negative reactions with a sensitive method over a period of a year is more acceptable as evidence of cure than two years of negative reactions in case of late secondary or early tertiary syphilis. The reason for this is found in the pathology of syphilis,

since in early cases we have every reason for expecting complete therapeutic success, whereas in the later stages spirochetes firmly entrenched in syphilitic exudates may escape therapeutic destruction, remain in a state of latency and escape detection over long periods of time.

But while we must wait for time to teach us the true value of the consistently negative complement-fixation reaction, something must be done for the present. We should have in mind definite ideas and opinions based upon present-day knowledge for advising our patients and guiding our therapeutic efforts. I am reasonably sure that patients with normal spinal fluids, yielding consistently negative blood reactions with a sensitive method and apparently free of all clinical signs and symptoms of syphilis, need not fear a relapse as long as the blood reactions remain negative. It is possible that in neuro- and cardiovascular syphilis, lesions may gradually develop even though the blood reactions are consistently negative; but if such is suspected in exceptional cases, an examination of the spinal fluid is indicated and if the latter yields negative colloidal gold and complement-fixation reactions, it is highly improbable that active syphilis is present, although I freely admit that latent spirochetes may be present under such conditions. In Chapter LXXIX I have discussed with more detail the curability of syphilis and the criteria of cure, since these subjects require thought and study from several different angles.

Proper Manner of Using the Complement-fixation Test as a Guide in the Treatment of Syphilis and as a Criterion of Cure.—Finally, a few words may be written on this subject. It is commonly stated that blood drawn after the completion of a course of treatment may yield a falsely negative result, whereas after a rest of two to four weeks the true reaction will be obtained. I have never been convinced of the truth of this statement and, indeed, my experience has been just the reverse. That is to say, blood complement-fixation tests conducted during and immediately after a course of treatment are more likely to yield positive reactions than after a period of a rest. And the reasons for this are not difficult to find. In the first place, surviving spirochetes may be active as a result of therapeutic stimulation and thereby furnish maximum amounts of complement-fixing "reagin" during or immediately after a course of treatment. In the second place, even though a course of treatment resulted in complete destruction of all spirochetes, time must be allowed for the elimination of the "reagin" in the blood. Just how long is required for the latter I am not able to state, as it varies of course with the amount to be eliminated; but in syphilitic rabbits cured with single doses of arsphenamin and neoarsphenamin it requires at least three to five weeks to reduce the "reagin" from the ++ level to negative. With human subjects yielding ++++ reactions I believe the matter of elimination to the negative level is a matter of months instead of weeks, but there is no definite way of measuring this more accurately since we can never be sure of cure as we may be in experimental infections of rabbits.

In 1911, Nichols and Craig[40] observed that Wassermann tests, made with blood drawn from strongly positive syphilitics within twenty-four hours after the ingestion of large amounts of beer or whiskey, sometimes reacted negatively and that these falsely negative reactions might continue for as long as three days. Others have apparently confirmed these observations, but I have not had the opportunity of studying the question under properly controlled conditions with human subjects.

My practice in using the complement-fixation test as a guide to treatment and as a criterion of cure is briefly as follows:

1. Blood is never drawn sooner than one week after acute alcoholism.

2. Tests are not made during a course of treatment except as a matter of special study and investigation, or to offer the patient the evidence of serological improvement.

3. Tests are made upon the completion of courses of treatment and again after rest periods.

4. After the last course of treatment, when it is believed that permanent negative blood reactions have been obtained, the tests are done every two months during the following year and every four months during the second year. In cases of chronic syphilis the tests are conducted thereafter, at least twice a year for several more years.

5. The examination of the spinal fluid for the complement-fixation and other examinations is advised and urged routinely in all cases of primary and secondary cases of syphilis after the first course of treatment. In chronic cases and especially those previously treated, these examinations are urged at the same time as the blood test when the patient first comes under observation. Spinal fluid examinations are again advised after the blood complement-fixation tests have yielded negative reactions for at least one year. However, this subject of spinal fluid changes in syphilis, and especially in relation to diagnosis and treatment, is a large and important one and is separately considered in a succeeding chapter.

CHAPTER XLI

PROVOCATIVE WASSERMANN TEST IN THE DIAGNOSIS OF SYPHILIS AND AS A CRITERION OF CURE WITH SPECIAL REFERENCE TO THE KOLMER COMPLEMENT-FIXATION REACTION

As stated in the preceding chapters, the degree of complement fixation in the Wassermann reaction tends to progressively diminish during the treatment of syphilis with such spirocheticidal compounds as arsphenamin, neoarsphenamin and allied substances as well as with mercury and bismuth. When treatment is begun in the early stages of the disease the decrease in complement fixation is usually progressive until negative reactions are observed. In the treatment of chronic syphilis, however, and especially of latent syphilis with weakly or moderately positive complement-fixation reactions, it is commonly observed that after treatment has been instituted the reactions first become stronger and that the decrease toward negative reactions is more irregular and sometimes broken by sudden and expected negative reactions followed by positive reactions or weakly positive by strongly positive reactions.

Complement fixation in syphilis is regarded as a result and an index of spirochetic activity, although the clinical evidence of a relation between the activity of lesions and the strength of the reactions is frequently lacking; in such cases, however, it is possible that spirochetes are active in physiologically unimportant tissues and while symptoms bear a relation to the location, size and degree of tissue involvement of syphilitic lesions, the quantity of complement-fixing "reagin" bears no relation to location but only to the numbers and degree of spirochetic activity. In "Wassermann-fast" cases of syphilis one is forced to conclude that active spirochetes are still present in the tissues, clinical evidence indicating involvement of the central nervous and cardiovascular systems in such cases; in other words anything increasing the degree of complement fixation in syphilis, that is, a real increase and not due to some technical variation, is to be ascribed primarily to some effect upon the spirochetes and apparently to an increase of their activity, since the Wassermann reaction is acceptable as an index of numbers and activity of these parasites.

As discussed in Chapter XXXV, there is much evidence to show that a variety of factors may provoke a Wassermann reaction in syphilis, but most interest in this chapter is centered upon the question of the influence of antisyphilitic treatment in this relation and whether or not the administration of arsphenamin, neoarsphenamin or mercury may be employed for the purpose of provoking a reaction as a means for the diagnosis of syphilis when the preliminary complement-fixation reaction is negative and as a final means for determining if complete cure has been effected.

Gennerich[1] is generally credited with having first made the observation that the administration of arsphenamin to cases of latent syphilis with negative Wassermann reactions is sometimes followed by a positive reaction and that the procedure may possess practical diagnostic value. He reported twelve cases, but in nearly all only one negative reaction was observed previous to the administration of salvarsan and the resulting "provocative" positive reactions were weak and occurred in from one to fifteen days after injection.

Lerrede[2] and Lier[3] followed some years later with confirmatory evidence and in this country Pease,[4] Craig,[5] Fordyce[6] and others accepted the general proposition that in some cases of latent and uncured syphilis, the administration of salvarsan resulted in the provocation of a positive Wassermann reaction and that the procedure possessed practical value for the diagnosis of chronic latent syphilis and as a test for cure. King[7] and Haller,[8] however, have thought the evidence incomplete and that the positive reactions occurring under such circumstances were due to technical variations in the Wassermann test, as well as to fluctuations in the amount of "reagin" in syphilis regardless of treatment as shown to occur by Boas[9] and Criag[10] and more recently by Browning and Kenneway[11] and Thaysen.[12]

In 1918 Stokes and O'Leary[13] greatly renewed interest in the subject by the study of 103 cases of latent and treated cases. Their plan was to inject intravenously 0.3 to 0.4 gm. arsphenamin or 0.6 gm. neoarsphenamin followed by repeated complement-fixation tests during the ensuing ten days. In 18.4 per cent. of these cases, presumptive but not conclusive evidence of provocative reactions was obtained. In two out of six cases this provocative test was thought of value as indicating unsufficient treatment. In active deep seated visceral, osseous and central nervous system syphilis, it was of less value for diagnosis than in latent syphilis and in cases presenting tertiary lesions of the skin and mucous membranes. Stokes and O'Leary clearly observed and reported, however, that both technical variations and variations in the reagin content of the blood were modifying factors and concluded that the provocative reaction appeared to be of little value in the absence of clinical evidence of the disease and inferior to both clinical judgement and the therapeutic test for the diagnosis of obscure cases.

This report was followed by that of Pollitzer and Spiegel,[14] who administered 0.2 gm. arsphenamin to 150 cases of syphilis presenting negative blood reactions after treatment. Wassermann tests were conducted before and 1, 3, 5, 7, 10 and 15 days after treatment, the series representing a great deal of work, but leading to the conclusion that, on account of various possible errors, no dependence can be placed upon a single positive reaction and that the procedure is useless and misleading.

Klauder,[15] however, had noted evidences of provocative reactions in the spinal fluids of some cases of syphilis in the secondary stage following the intravenous injection of arsphenamin which was in confirmation of the earlier observations of Altman and Dreyfus[16] and Gennerich.[17] In a later study of a larger group of chronic and latent cases of syphilis, Solomon and Klauder[18] observed provocative reactions in the spinal and ventricular fluids of some cases of chronic syphilis after the intravenous and intraspinous injections of arsphenamin consisting of an increase of cells and protein as well as positive complement-fixation reactions. In none of these cases, however, were provocative blood reactions observed, but it was believed that the provocative spinal fluid changes were occasionally of value in aiding the diagnosis of obscure cases.

In the meantime Uddgren[19] published observations tending to show that the intramuscular injection of sterile milk in doses of 5 to 10 c.c. provoked positive Wassermann reactions in some cases of latent syphilis, probably due to non-specific stimulation of latent foci of spirochetes and analogous in this respect to the stimulation of a latent case of syphilis by trauma caused by a bullet and the injection of tetanus antitoxin, occurring in the practice of Dr. Pelouze, of Philadelphia, and recorded by Klauder.[20]

Finally, O'Leary[21] in a second study of 285 cases in the Mayo Clinic, observed apparently true provocative reactions in 8 per cent. of cases following the intravenous injection of 0.3 gm. of arsphenamin with a series of seven complement-fixation tests thereafter, at intervals of twenty-four hours. Mention may also be made of the investigation of Frei[22] who commonly observed an apparent increase of spirochetes in the chancres of a number of cases following the intravenous injection of salvarsan and interpreted as indicating the direct spirocheticidal activity of this substance, the study having been undertaken to throw additional light upon the mechanism of the action of salvarsan in syphilis.

This brief review of the literature indicates, therefore, a considerable difference of opinion regarding the question of whether the administration of arsphenamin or neoarsphenamin actually does provoke positive complement-fixation reactions in latent and uncured syphilis or whether such apparent reactions are due rather to technical variations and fluctuations of the Wassermann "reagin" in the blood independent of the injection; also regarding the practical or clinical value of the provocative complement-fixation reaction in the diagnosis of obscure cases of syphilis and as a test of cure, granting that true provocative reactions occur.

During the past two years, I have been much interested in a study of the subject with my new complement-fixation test, believing that its quantitative character and precautions against technical errors may yield additional

information. The results of these studies are briefly summarized in the balance of this chapter and likewise my general conclusions upon the whole subject of the provocative Wassermann reaction based thereon.

Variations in the Degree of the Complement-fixation Reaction Due to Technic.—Unquestionably minor degrees of variation in the degree of complement-fixation are due to technical factors over which there is no adequate control under routine conditions. These variations are largely due to variations in the complement serum and to lesser extent to variations in the anticomplementary activity of human sera providing the same antigen is employed in all tests. If, however, different antigens are employed in tests of the serum of the same individual at different times over a period of observation, a new and important additional factor of variation is introduced.

With my new method however, the degree of variation presumably due to technic is very slight and usually elicited only in the smaller doses of serum. I have, for example, frequently taken specimens of blood each day for eight to ten days from cases of tertiary and latent syphilis and conducted tests each day and again repeated all of the tests on the same day with the same complement, same antigen, etc., with specimens of each serum carried over at o°C. The following results observed with one case of chronic untreated latent syphilis is representative of the series:

Daily tests with specimens of serum yielded the following reactions:

Serum C.C.	Days									
	1	2	3	4	5	6	7	8	9	10
0.1	4*	4	4	4	4	4	4	4	4	4
0.05	4	4	4	4	4	3	4	4	4	3
0.025	2	1	2	2	1	2	1	1	2	1
0.005	–	–	–	–	–	–	–	–	–	–
0.0025	–	–	–	–	–	–	–	–	–	–

*4 = ++++; 3 = +++; 2 = ++; 1 = +.

The results of tests conducted with all ten specimens of serum on the same day yielded the following reactions:

Serum C.C.	Days									
	1	2	3	4	5	6	7	8	9	10
0.1	4	4	4	4	4	4	4	4	4	4
0.05	4	4	4	4	4	4	4	4	4	4
0.025	4	4	2	2	2	1	1	1	2	1
0.005	–	–	–	–	–	–	–	–	–	–
0.0025	–	–	–	–	–	–	–	–	–	–

It will be observed, therefore, that the reactions were slightly stronger in this set of tests with the first and second day sera, due, presumably, to the acquisition of slightly increased anticomplementary properties of these sera even though the serum controls were completely hemolysed.

It will be noted, however, that such uniform results were observed only in selected chronic untreated latent cases of syphilis, which are the only ones suitable for tests of this kind in order to reduce to a minimum variations in the degree of complement-fixation due to possible fluctuations in the amounts of "reagin" in the blood. In such cases the new test has yielded remarkably uniform reactions, the same antigen being used in the same dosage in all tests. As previously stated, the fluctuations were observed only in the higher dilutions of serum and never in the larger doses as 0.1 and 0.05 c.c. of cases yielding strongly positive reactions.

Variations in the Degree of Complement-fixation Reactions Due to Fluctuations in Antibody.—My studies in this subject have been confined to untreated chronic cases of syphilis, as there is an abundance of evidence to show that in untreated acute syphilis in the primary and secondary stages the complement-fixation reactions fluctuate, but with a tendency to become stronger and stronger. The general result has been to show that, in *tertiary syphilis with active lesions*, a marked variation in the degree of complement-fixation occurs which may be reasonably ascribed in most part to fluctuations in the "reagin" content of the serum.

For example, in a case presenting an ulcerating gumma of the nose, the reactions conducted with ten specimens of serum collected over a period of seventeen days but all tested at the same time in order to reduce to a minimum fluctuations due to technic, were as follow:

Serum C.C.	Days									
	1	2	3	5	6	9	11	12	14	17
0.1	4	4	4	4	4	4	4	4	4	4
0.05	4	4	3	4	4	2	3	4	4	4
0.025	4	4	–	4	3	–	–	1	2	1
0.005	2	1	–	–	–	–	–	–	–	–
0.0025	–	–	–	–	–	–	–	–	–	–

It will be observed that the fluctuations occurred principally with the smaller doses of serum and I have not yet observed a case of untreated syphilis that yielded a strongly positive reaction one day and a negative reaction the following day, although with weakly reacting sera this was sometimes observed, as shown in the following results of tests conducted on one day with six specimens of sera collected over a period of eleven days from a case of untreated chronic syphilis showing beginning optic atrophy:

Serum C.C.	Days					
	1	2	5	9	10	11
0.1	2	2	–	2	1	2
0.05	–	–	–	–	–	–
0.025	–	–	–	–	–	–
0.005	–	–	–	–	–	–
0.0025	–	–	–	–	–	–

In tests conducted over longer periods of time the fluctuations in degree of complement-fixation were more marked; in these cases, however, the tests were conducted with each separate specimen of serum about forty-eight hours after bleeding and for this reason introduced the added technical factors of variation ascribed to the use of different complement sera, as well as, possibly, to minor and undetectable changes in the antigenic activity of the extract employed as antigen. The results of one such case presenting chronic syphilitic aortitis and myocarditis but in whom treatment could not be undertaken at the time owing to deficient urinary elimination due to chronic nephritis, were as follows over a period of 35 days:

Serum C.C.	Days						
	1	5	8	10	14	21	35
0.1	4	4	4	4	4	4	4
0.05	4	3	4	1	4	4	4
0.025	–	–	1	–	2	–	–
0.005	–	–	–	–	–	–	–
0.0025	–	–	–	–	–	–	–

In *chronic latent syphilis* the fluctuations are less marked, my tests having been conducted with the sera of untreated syphilitic multiparous women presenting no other evidences of syphilis than syphilitic progeny and positive complement-fixation reactions. In one such case, examined about two years after the last pregnancy, the reactions were as follows, the tests being conducted separately over a period of 42 days and therefore, including technical variations:

Serum C.C.	Days								
	1	2	5	9	17	21	28	36	42
0.1	3	4	3	1	1	2	3	4	3
0.05	1	1	2	–	–	1	–	2	–
0.025	–	–	–	–	–	–	–	–	–
0.005	–	–	–	–	–	–	–	–	–
0.0025	–	–	–	–	–	–	–	–	–

I believe, therefore, that it may be accepted without reserve that the Wassermann reaction varies in the degree of complement fixation due to fluctuations of the "reagin" content of the sera. Undoubtedly a portion of this variation is due to the technical factors mentioned above but allowing for these we cannot escape the conclusion that the amount of "Wassermann substance" or "reagin" likewise fluctuates and is responsible for varying degrees of complement fixation. This fluctuation may not be detected with daily specimens of blood over a period of less than a week, but is well defined with tests conducted over a period of several weeks or months. This is especially true in chronic syphilis presenting active lesions; it is less apparent in chronic latent syphilis. In both groups, however, variation in complement fixation may bear no relation to the clinical condition of the patient. That is to say, the reaction may be strongly positive at one time and weaker at another without coincident clinical manifestations of exacerbation or regression of the disease or a particular lesion. In my experience, the new method employed in these studies has shown less variation than my former method employing three antigens and, in the latter, cholesterolized antigens showed less variation than antigens of aceton insoluble lipoids and plain alcoholic extracts of syphilitic liver or beef heart. These differences are ascribed to the use of a new antigen of superior qualities in the new method, together with a combined primary incubation of 18 hours at 6 to 8°C. followed by ten minutes in a water-bath at 38°C., as well as to the method employed of preparing and titrating the complement serum and to other technical factors of lesser importance.

Variations in the Degree of Complement-fixation Reactions Due to Treatment.—These have been previously referred to in Chapter XL. In the treatment of acute syphilis embracing the primary and secondary stages, the variations in degree of complement fixation are not extreme, but in the treatment of chronic syphilis both active and latent, extreme variations are sometimes encountered and especially after treatment has been underway for several months. One commonly observes that, during the first few weeks of treatment of chronic syphilis the reactions become stronger followed by a gradual decrease in complement fixation to negative reactions, but with, frequent exacerbations; in the co-called "Wassermann-fast" cases, however much less variation in the degrees of complement fixation is observed.

Diagnostic Value of the Provocative Complement-fixation Reaction in Syphilis.—I believe that it must be admitted that spirocheticidal drugs, and especially arsphenamin and neoarsphenamin, are capable in subcurative doses of disturbing foci of spirochetic infection with an exacerbation of their

activities. The Jarisch-Herxheimer reaction is commonly believed to be a phenomenon of this kind and the provocative Wassermann reactions have been considered of this same general nature although Stokes and O'Leary have observed no constant relation between clinical exacerbation (Jarisch-Herxheimer reactions) and positive provocative complement-fixation reactions.

But my experience coincides with that of Stokes and O'Leary that provocative reactions are only likely to occur in the presence of clinical evidences of syphilis and not in latent syphilis. In other words, the provocative complement-fixation reaction requires that there be present in the tissues a minimal number of spirochetes to be provoked into activity for the production of the complement fixing "reagin." In not a few cases of chronic latent syphilis and especially of treated cases, this condition may not be present. Furthermore, the spirochetes must be readily accessible to the arsphenamin or neoarsphenamin and while at first thought this may not appear to be of much importance, yet the provocative test is usually conducted by the administration of single doses and in chronic syphilis it may well be that a single dose of arsphenamin or neoarsphenamin is eliminated before appreciable spirochetic effects are brought about.

I believe, therefore, that the provocative Wassermann reaction by the administration of arsphenamin or neoarsphenamin is a demonstrated fact, but its practical diagnostic value is an entirely different matter. In chronic syphilis with lesions the injection of a single dose of arsphenamin or neoarsphenamin has in my experience undoubtedly increased the strength of the new complement-fixation reaction, but in latent syphilis with two to five preliminary negative reactions, I have not yet observed convincing evidence of a provocative reaction with blood serum after single doses of arsphenamin or neoarsphenamin and have had no experience with spinal fluids in this particular regard.

In other words, if a patient presents a lesion that may be syphilitic but with a negative-complement fixation reaction, I believe that it is decidedly worth while to administer arsphenamin or neoarsphenamin after the plan described below; in such cases positive serum reactions have been provoked and at the same time a therapeutic test is made which may be even more valuable for diagnosis.

But in latent syphilis without manifest lesions I do not regard the test with single injections of drug as worth while despite the fact that one may occasionally elicit very weakly positive reactions; in some such cases a series of doses of neoarsphenamin has yielded more conclusive evidence and if one is reasonably assured that the individual is syphilitic, as may be true with the mothers of syphilitic children, no harm is done by the administration of several doses; otherwise I agree with Shepardson[23] that just as much or more can be accomplished for diagnosis by conducting occasional complement-fixation reactions by a sensitive method without resorting to the provocative procedure.

Sometimes the administration of a dose or two of arsphenamin or neoarsphenamin is followed by clinical exacerbations of syphilis and I believe that the physician should always keep such individuals under observation for several weeks at least and be prepared to proceed at once with active treatment if such occurs. In latent syphilis of the aged or of individuals with nephritis or some such condition rendering inadvisable the institution of active treatment, my advice is not to employ provocative injections but to leave alone what is good enough at least for the time.

Value of the Provocative Complement-fixation Reaction as an Index of the Cure of Syphilis.—While the provocative procedure may be of aid in the diagnosis of obscure lesions of syphilis and especially if a series of injections of neoarsphenamin are given, I have observed no value whatsoever to provocative tests with *single* doses of arsphenamin or neoarsphenamin as a criterion of cure. Here again, however, the administration of three doses of neoarsphenamin has sometimes resulted in provoking weakly positive reactions with the sera of individuals who had finished courses of active treatment with repeated negative reactions during periods of rest. For this reason, I always conduct frequent tests during the last one or two courses of treatment given routinely after the complement-fixation reaction has first become negative, because if positive reactions are observed it is taken as an indication for a more thorough course of treatment than would otherwise be indicated.

After the complement-fixation test has yielded a series of negative reactions, accompanied by clinical evidences of cure insofar as these may be ascertained, I believe that complement-fixation tests at periodical intervals of three or four months for the ensuing two years are sufficient and that provocative tests employing single doses of arsphenamin or neoarsphenamin as usually conducted are useless and may give a false sense of security.

Author's Method for Conducting the Provocative Complement-fixation Reaction.—If the provocative procedure is employed as an aid in the diagnosis of an active lesion of obscure origin, of chronic latent syphilis or possibly as a test of cure, I believe that at least two or three doses of neoarsphenamin should be given. In the majority of cases in which this test is employed, there are usually good reasons for suspecting syphilis and at any rate the injection of neoarsphenamin cannot be said to be dangerous or harmful. Just how long one should wait after the injections before drawing blood for the tests cannot be stated as it involves the question of how rapidly the "reagin" is produced. Under ordinary circumstances the procedure is apt to be too expensive for many individuals and for this reason the number of tests should be reduced to a minimum. My own practice is as follows, the test being applied only to occasional and exceptional cases and especially those presenting clinical manifestations or a history suspicious of syphilis:

(*a*) The intravenous injection of 0.6 gm. neoarsphenamin dissolved in 20 c.c. of sterile distilled water.

(*b*) Blood withdrawn 48 hours later and the complement fixation test conducted; if the reaction is negative:

(*c*) A second intravenous injection of 0.6 gm. neoarsphenamin five days after the first.

(*d*) Blood withdrawn 48 hours later and the complement-fixation test conducted.

Sometimes this is sufficient if a positive reaction is observed, but under these circumstances the result is checked up by a third test. If, however, the reaction is negative, a third injection of neoarsphenamin is given followed by a blood test forty-eight hours later. If this test yields a negative reaction a final blood test is taken five days later or from seven to ten days after the last injection. All of the complement-fixation tests are conducted according to the technic of my new quantitive test employing varying amounts of serum, as this test has been demonstrated to possess a very high degree of sensitiveness combined with specificity for syphilis. It is important to employ a sensitive test for results; tests conducted in the usual manner with primary periods of incubation of one hour in water bath or incubator are not nearly as satisfactory because lacking in sensitiveness and especially if plain

alcoholic extracts of syphilitic liver, beef or guinea-pig heart are employed as antigens.

CHAPTER XLII

CEREBROSPINAL FLUID CHANGES IN RELATION TO THE DIAGNOSIS AND TREATMENT OF SYPHILIS

The detection of invasion and infection of the organs of the central nervous system with *Spirochæta pallida* is greatly aided by the examination of the cerebrospinal fluid. The positive blood complement-fixation reaction indicates a general invasion and infection of the body, but in early syphilis may afford no evidence of the involvement of any particular organ or tissue, and clinical and roentgenological evidences of infection are not usually to be elicited until the disease has been well established with the production of chronic lesions. However, infection of the meninges, and even of the substance of the brain and cord, may be detected by appropriate examinations of the spinal fluid during the first stage of infection of these tissues. Indeed, it is probable that in some cases, at least, the spinal fluid changes in the late primary and secondary stages of syphilis are due merely to invasion of these organs with *Spirochæta pallida* during the acute spirochetemic stage of the disease, without infection of their tissues, since permanent localization and survival of the parasites may be prevented by local factors of resistance.

Spirochetic Invasion versus Infection of the Central Nervous System.—In other words, a distinction should be made between the invasion and the infection of organs with *Spirochæta pallida*, just as we do in bacterial diseases. In the former, the parasites gain access to the tissues and may even produce temporary disturbances, but are destroyed or dislodged by natural immunological agencies before tissue changes occur and infection established. Studies of the cerebrospinal fluid, which I shall review shortly, have indicated

that, during the acute stages of syphilis and particularly the late primary and secondary stages, evidences of spirochetic invasion of the meninges and other tissues of the central nervous system are to be found in at least 30 to 40 per cent. of cases; treatment, and especially the active and continuous administration of arsphenamin and neoarsphenamin for six or more doses, reduces the incidence of these changes to 15 to 25 per cent., but even in some untreated cases of syphilis these changes disappear spontaneously, indicating that while the tissues may be invaded by *Spirochæta pallida*, infection does not necessarily follow. It is doubtful if the administration of pills of protiodid of mercury in the old method of treating syphilis resulted in exerting sufficient spirocheticidal activity to actually prevent infection of the tissues of the central nervous system after invasion had occurred; yet the incidence of syphilis of these organs under this old plan was probably not over 10 per cent. and especially in the negro, indicating that natural resistance of these tissues may, in some cases, at least, prevent infection even though invasion has occurred. However, when invasion has occurred to the extent of producing pleocytosis and an increase of proteins in the cerebrospinal fluid, the danger of infection is imminent unless the parasites are promptly destroyed by chemotherapeutic measures. Some physicians believe, however, that active medication may actually aid in producing infection of these tissues at this time by breaking down the natural protective agencies, by preventing the production of antibodies or producing breaks in the capillaries, but I shall discuss these hypothetical questions below. The point I wish to make here is that, in my opinion, the examination of the spinal fluid has been brought up to such a state of perfection at present, that invasion of the central nervous system with spirochetes may be detected in the majority of cases of early syphilis, but that the evidences of this invasion do not necessarily mean that infection will occur with the development of lesions producing clinical neurosyphilis and especially if syphilis is properly treated during its early stages.

There is no reason to doubt that the tissues of the central nervous system are invaded with spirochetes in all cases of syphilis in which spirochetemia develops. The same is probably true of all other vascularized tissues of the body. It is interesting, however, that spirochetic invasion of the brain, cord and meninges produces spinal fluid changes in the majority of cases and that the spirochetes themselves may be actually found in the fluid even in the primary and secondary stages of syphilis. But even in those cases whose spinal fluid shows no changes, spirochetic invasion cannot be excluded; indeed, spirochetes have been found in the spinal fluids of such by rabbit inoculation. I see no reason, therefore, for spinal puncture and the examination of spinal fluid for evidences of neural invasion and infection until sufficient treatment has been given to sterilize the blood; after this time, however, in practice after the first course of treatment, examination of the spinal fluid is indicated for the detection of those cases in whom the spirochetes have succeeded in remaining in the tissues and escaping destruction.

Just what factors determine whether or not infection will occur after invasion has taken place—that is, whether or not spirochetes will lodge in the tissues and produce lesions after being brought to them by the blood—cannot be stated, just as we are unable to explain at present why spirochetes locate mainly in the myocardium and aorta of some cases, in the liver in others, etc. It may be that some strains have a specific tissue affinity for certain organs, that localization may be determined by preceding tissue injury lowering local resistance or favoring blood stasis, but these subjects have been already discussed in Chapter XXXVII. Very probably the

natural resistance of different organs varies considerably in resistance to infection after being invaded by *Spirochæta pallida* and that the tissues are not equally protected by the general reaction which occurs during the early stages of syphilitic infection; I believe such factors, together with preceding tissue injuries reducing local resistance or favoring blood stasis, are the important determining factors governing infection of the central nervous system as well as other organs of the body. At any rate, in cases of neurosyphilis, spirochetic infection may be found in other parts of the body as shown by Fordyce,[1] Stokes,[2] Wile,[3] Frisch[4] and others; aortitis, myocarditis and even skin and periosteal lesions are frequently associated, all due to the same strain and constituting very positive evidence against the acceptance of the theory of specific neurotropism of strains of *Spirochæta pallida*. Treatment of syphilis at the time of initial neural invasion is, however, of great importance, since it would appear from the investigations of Wile, Moore, Keidel, Stokes and others shortly to be reviewed, that prompt destruction of the spirochetes at the time of invasion reduces the chances of infection of these tissues just as it does of other organs. In my opinion there is no evidence at all to indicate that arsphenamin or neoarsphenamin, administered in a proper manner, results in actually aiding infection of the central nervous system (neurofixation) during the early stages of syphilis, as claimed by Mallein, Tzanck and Kesmorgant[5] and others, by reducing antibody production or producing minute injuries of the capillaries.

Spirochæta Pallida versus Spirochetic Toxins in the Etiology of Neurosyphilis.—Prior to 1913, when Noguchi and Moore[6] discovered *Spirochæta pallida* in the brains of twelve cases of paresis, the majority of neurologists were of the opinion that syphilis played some etiological rôle in at least some cases of paresis and tabes, but the relationship of *Spirochæta pallida* to these diseases was not clearly established and they were commonly designated as parasyphilitic or metasyphilitic diseases. This discovery was quickly confirmed by Levaditi, Marie and Bankowski,[7] who found *Spirochæta pallida* in the fresh substance of eight in a series of nine paretic brains, and since then confirmatory evidence has been supplied by the investigations of Nichols and Hough,[8] Graves,[9] Wile[10] and others. Noguchi also found *Spirochæta pallida* in the spinal cords of a few tabetics; Reasoner[11] in the brain of an early case of cerebral syphilis; Kiely[12] in the cerebral cortex of congenital syphilis, etc. Except in paresis, however, the number of spirochetes to be found in the meninges, spinal cord, etc., are very small and their demonstration usually requires prolonged search of a large number of stained sections.

While Uhlenhuth and Mulzer[13] failed to demonstrate *Spirochæta pallida* in the spinal fluids of cases of paresis and tabes by inoculation into rabbits, they were later successful with the fluid of a case of early cerebrospinal syphilis, and since then Hoffmann, Nichols and Hough, Steiner,[14] Volk,[15] Artz and Kerl,[16] Fruhwald and Zaloziecki[17] and others have reported positive results. In this country, Wile[18] has made particularly valuable studies reporting successful rabbit inoculations with as high as 62½ per cent. of spinal fluids from cases of early syphilis, of tabes and of paresis. More recently Wile and Kirchner[19] have demonstrated spirochetes in the spinal fluid of cases of syphilis in the primary and secondary stages of the disease, as well as in cases of chronic neurosyphilis, by sections of coagula produced by a modification of the Alzheimer method and stained by the Warthin-Starry silver agar method. Just what governs the access of spirochetes to the spinal fluid cannot be stated, but probably this is determined by the degree of spirochetemia and the migration of parasites from the perivascular lymph spaces. If perivascular invasion is extensive it is readily understood how spirochetes may be washed by a more or less mechanical manner into the secretions of the choroid plexes or by extravasation of plasma from the vessels of the meninges and particularly of the pia into the spinal fluid. This is particularly true if *Spirochæta pallida* excites some inflammatory changes in these tissues with serous exudation. Investigations of this kind indicate, therefore, that *Spirochæta pallida*, rather than hypothetical toxins produced in some other focus of syphilitic infection and carried to the central nervous system, is directly and primarily responsible for the lesions.

With the syphilitic psychoses the evidence is less conclusive, but data at hand indicate that *Spirochæta pallida* produces but little diffusible toxin and it is highly probable that the true psychoses of syphilis are likewise due to the actual presence of spirochetes in the brain rather than to the influence of toxins or toxic substances produced by spirochetes or the disintegration of syphilitic exudates elsewhere in the body and transported to the central nervous system by the blood and lymphatic systems.

Anatomical and Clinical Classification of Neurosyphilis.—No subject in syphilis is more perplexing from the standpoint of classification of lesions and symptom-complexes than syphilis of the nervous system. For this reason the term "neurosyphilis" has come into general use for designating a wide variety of lesions and diseases of the nervous system and particularly of the central organs due to syphilitic infection. For example, the term includes lesions of the peripheral nervous system, embracing the cranial and peripheral nerves, their ganglia and end organs, as well as the sympathetic nerves, their ganglia and terminal arborizations; likewise lesions of the brain, spinal cord and meninges, constituting "central neurosyphilis." From the pathological standpoint we hear of vascular neurosyphilis, parenchymatous neurosyphilis, diffuse neurosyphilis, gummatous neurosyphilis, etc. From the clinical standpoint the terms are even more numerous and perplexing, the commoner being paresis, paretic neurosyphilis or general paralysis of the insane; tabes dorsalis, or locomotor ataxia, taboparesis, cerebrospinal syphilis, cerebral syphilis, cerebrospinal sclerosis, syphilitic arteriosclerosis and thrombosis, etc., etc., as well as many more terms to include the mental or psychic disturbances as syphilitic paranoia, tabetic psychosis, syphilitic neurasthenia, "paresis sine paresi," etc., etc.

In other words, *Spirochæta pallida* may infect any portion of the nervous system and depending upon the anatomical location of the lesions we have a pathological classification; according to the signs and symptoms produced we have a clinical classification.

I would not have presumed to touch upon this intricate matter of classification of neurosyphilis, were it not necessary to do so for the adequate discussion of cerebrospinal fluid changes in syphilis and especially in relation to chemotherapy. To discuss the whole subject under the general term "neurosyphilis" is not sufficient because an adequate knowledge of the fundamental pathological changes is required for the proper evaluation of the results of examination of the spinal fluid as a means of diagnosis, as a guide in treatment and an index of cure; indeed, such knowledge is likewise indispensable for the proper evaluation of therapeutic measures and in relation to prognosis. Some physicians cannot understand why the Wassermann test with spinal fluid should yield a negative reaction in some cases of neurosyphilis or why the cells are almost within normal limits in some cases and increased in others. In no other system may there be such appalling discrepancies between clinical and laboratory findings as in neurosyphilis and yet a few minutes of thought on the subject is sufficient for an understanding of the chief reason, namely, in no other system may size and location of syphilitic lesions so profoundly influence the clinical signs and symptoms.

I do not believe, however, that it is necessary for the general practitioner to have in mind the elaborate classifications of the neuropathologist or the clinical neurologist and psychiatrist. It is sufficient to remember that *Spirochæta pallida* may locate primarily in the meninges, in the substance of the brain or cord, in or about the blood-vessels or in all three at the same time, producing respectively, meningeal, parenchymatous, vascular and diffuse neurosyphilis. The lesions may be general or local and are usually multiple; they are seldom of pure types. For example, meningeal syphilis may involve the parenchyma and parenchymatous syphilis almost always involves the overlying pia mater. It is for this reason that systematists have been compelled to adopt rather lengthy classifications. My own working classification has been largely based upon the excellent classifications of Southard and Solomon and is here given for any aid it may be to others:

Anatomical	Clinical
Meningeal neurosyphilis (changes principally in the meninges)	1. Acute and chronic cerebral or cerebrospinal syphilitic meningitis (so-called cerebrospinal syphilis)
	2. Chronic localized syphilitic meningitis which may result in: Gumma of meninges; Cranial nerve palsies; Bulbar palsy; Neuritis and muscular atrophy; Transverse myelitis; Epilepsy
Vascular neurosyphilis (changes principally in the blood-vessels)	1. General syphilitic arteriosclerosis
	2. Localized syphilitic arteriosclerosis which may result in: Apoplexy; Aneurysm; Cerebral thrombosis and epilepsy
Parenchymatous neurosyphilis (changes principally in the substance of brain or cord)	1. General syphilitic sclerosis of brain and cord (cerebrospinal sclerosis) with gummas
	2. More or less localized syphilitic sclerosis with nerve cell destruction: Paranoia; Chorea; Epilepsy; Muscular atrophy
Diffuse neurosyphilis (mixtures of meningeal, vascular and parenchymatous)	1. Paresis, congenital ("juvenile paresis") and acquired ("general paresis;" "dementia paralytica," "softening of the brain")
	2. Tabes dorsalis and tabetic psychosis
	3. Taboparesis
	4. Erb's syphilitic spastic spinal palsy
	5. Some cases of cerebrospinal syphilis

Spinal fluid examinations in conjunction with the blood Wassermann test usually furnish sufficient data for establishing the general diagnosis of syphilis of the central nervous system, but for purposes of differential diagnosis are of aid only when the results are interpreted with the clinical signs and symptoms. In other words, there are no pathognomonic signs of any one syphilitic disease of the nervous system to be found in the spinal fluid; probably the colloidal gold reaction in paresis most nearly approaches this state, but in some other non paretic syphilitic diseases a similar gold curve may be produced. In many cases, probably the majority, a sufficiently accurate diagnosis of neurosyphilis with determination of the location of the lesion or lesions may be made by ordinary neurological examination embracing the papillary reactions, various reflexes, gait, station, etc., together with spinal fluid examination; in others, however, prolonged experience and expert knowledge are required, and especially in the diagnosis of the psychoses and their differentiation from organic diseases, as manic depressive psychosis and dementia precox from paresis, etc., etc.

Pathology of Neurosyphilis in Relation to Spinal Fluid Changes.—As previously stated, the lesions of neurosyphilis are due to the presence of *Spirochæta pallida* rather than to some hypothetical toxin produced elsewhere in the body and transported to these tissues. The parasites are brought to the tissues of the central nervous system by the blood and there is no reason to doubt but that this occurs in all cases of untreated syphilis passing through the primary and secondary stages of the disease. In those cases in whom this initial invasion is followed by infection or those whose tissues are invaded and infected during temporary periods of spirochetemia in the late stages of syphilis, which I believe may occur, the spirochetes lodge in the perivascular tissues. From this time on the fate of the individual depends upon the numbers, invasiveness and virulence of the spirochetes. If the parasites are but feebly invasive and virulent, they may progress no further and vascular lesions of sclerosis result; if the parasites are highly invasive and virulent, they may migrate with the involvement of surround-

ing tissues producing more diffuse lesions of the meninges or parenchymatous structures.

The resulting lesions are essentially similar in their histological characteristics. *Spirochæta pallida* exerts positive chemotaxis upon small lymphocytes and the areas of syphilitic infection are infiltrated and surrounded with these cells. Plasma cells are likewise found. Congestion with serous exudation occurs as in other inflammations, and as a result both cells and serous inflammatory fluids may find their way into the sipinal fluid, producing an increase of cells (pleocytosis) and proteins. Hence, the degree of these changes varies with the acuteness of infection, being most marked in the early stages of the process because fibrous tissue is laid down later in and about the lesions as in all chronic inflammations which tends to reduce cellular and serous exudation. As the result of poisonous products of the spirochetes plus a reduction in nutrition due to endarteritis and lymphocytic crowding, the tissue cells of the infected areas may be destroyed with consequent impairment or loss of function. Doubtless, the products of this disintegrative process reach the spinal fluid, producing other changes in the organic and inorganic constituents which are detected only by elaborate chemical analyses.

It is surprising, however, how much damage may be noted upon histological examination of the tissues with so few spirochetes to be found. Doubtless, however, spirochetes tend to die and undergo autolysis during the fibrotic stage of the lesions and the scarcity of their numbers in chronic lesions of the nervous system (paresis excepted) is analogous to conditions in syphilitic lesions elsewhere in the body. Doubtless more spirochetes would be found if it were possible to examine the early lesions and especially if the tissues could be fixed within an hour or two after death. However, one never ceases to wonder at the amount of tissue change, and especially the degree of fibrosis, that may be brought about by what must be relatively few parasites. Of course, in the central nervous system, extensive tract degeneration and fibrosis may be due to a small lesion involving the tract at one point with descending or ascending degeneration from this point. For this reason the examination of numerous serial sections of tissue may be required, before foci of infection are discovered.

Almost needless to state, the degree and, to a lesser extent, the kind, of spinal fluid changes in neurosyphilis vary according to the situation and size of the lesions. The cells and proteins are especially increased when the meninges are involved and the amount of increase is almost an index of the degree of meningeal involvement; the colloidal gold and complement-fixation reactions, however, are more influenced by the degree of parenchymatous involvement.

Nowhere else in the body may there be such a lack of conformity between signs and symptoms of disease and laboratory findings as in neurosyphilis. For example, in tabes dorsalis and Erb's spastic paraplegia the initial sclerosis of the posterior nerve roots followed by sclerosis of the posterior columns may produce the most marked signs of disease and yet the lesions are so small and of such a kind that the cerebrospinal fluid changes are apt to be slight and, indeed, may not be appreciable at all in some cases.

The same is true in some other syphilitic lesions of the central nervous system. For example, a small patch of syphilitic infection involving a cranial nerve may bring about a palsy, producing marked signs and symptoms, and yet the lesion may, on account of its small size or situation, produce no demonstrable changes in the spinal fluid. A gumma of the meninges may do a great deal of mischief with muscular atrophy and other changes

due to involvement of spinal tracts and nerves, and yet the actual degree of pathological changes may be so slight that abnormalities in the spinal fluid cannot be elicited; even extensive tract degeneration with fibrosis (gliosis) may produce no increase of cells or of protein, although other changes in the chemistry of the spinal fluid may occur, which, however, cannot be detected by simple routine examinations.

Therefore, *it should never be overlooked by clinicians that negative spinal fluid findings do not exclude the possible syphilitic nature of a lesion or a disease;* Solomon and Klauder[20] have especially directed attention to the possibility of negative spinal fluid findings in some cases of neurosyphilis and particularly in vascular lesions, as well as in tabes, cerebral gumma, cerebral nerve palsies, syphilitic epilepsy and the psychoses, as syphilitic paranoia and syphilitic dementia. Just as I have emphasized in the preceding chapter that a negative blood-complement-fixation reaction does not exclude syphilis, the same may be said of the spinal fluid. However, owing to the fact that the spinal fluid may be used in larger amounts than serum, the complement-fixation test with it yields a more sensitive reaction, and a negative result, therefore, should carry more weight in excluding syphilis; furthermore, the chances for non-specific or falsely positive reactions are much less than in tests employing serum.

Cerebrospinal Fluid Examinations of Value in the Diagnosis and Treatment of Neurosyphilis.—From the standpoint of easily applied tests, the following are of value: (*a*) changes in pressure; (*b*) changes in physical appearance; (*c*) total number and kinds of cells; (*d*) chemical changes with special reference to proteins and sugar; (*e*) serological changes with special reference to the presence of antisheep hemolysin (Weil-Kaffka reaction), the complement-fixation, colloidal gold and colloidal mastic reactions. It is my custom to record the pressure, amount of fluid removed, physical appearance of the fluid, total cells per cubic millimeter, etc., on all cases examined, the chart shown (Chart 5) devised for these records, being found very useful. But in a treatise of this kind space does not permit of a detailed discussion of the technic and diagnostic significance of these tests although brief mention may be made of the two most valuable ones, namely, the complement-fixation and colloidal gold reactions.

Cerebrospinal fluid for these examinations is usually secured by spinal puncture in the lumbar region, the technic being described in Chapter LXI. It is possible that fluid secured at this level is not representative of the whole cerebrospinal fluid as indicated by the investigation of Solomon and Welles,[21] who found marked differences in the cytology, chemistry and serology of ventricular and lumbar sac fluids in the same cases; Schoenfeld[22] found no differences in fluids drawn off at four different levels between the eleventh dorsal and fifth lumbar vertebrae. Experience has shown that examination of the fluid secured by lumbar puncture yields extremely valuable diagnostic data and is the best available for routine examinations.

Wassermann Reaction with Cerebrospinal Fluid in Syphilis, with Special Reference to the Kolmer Complement-fixation Reactions.—One of the most valuable tests for neurosyphilis is the complement-fixation test with cerebrospinal fluid. The Sachs-Georgi, Kahn and other precipitation tests, while technically simpler, have not proven sufficiently sensitive. In the original Wassermann test the spinal fluid was employed in dose of 0.4 c.c., but we now know that this amount was too small and that with this technic doses as high as 1.5 c.c. may be employed with perfect safety and greatly increase the percentage of true positive reactions.

EXAMINED BY:

In my new method a dose of 0.5 c.c. of spinal fluid corresponds to about 1.5 to 2.0 c.c. in the original Wassermann test, just as 0.1 c.c. of serum in my method corresponds to 0.3 to 0.4 c.c. in the original test, when calculations are based upon the relative amounts of complement employed in each. In my new method the first dose is 0.5 c.c., which greatly increases the sensitiveness of the reaction; indeed, one may use 1 c.c. of fresh fluids with safety and increase the specific sensitiveness of the reactions to a slightly greater degree. Apparently non-specific reactions are not nearly as likely to occur with spinal fluid as with serum, and, since they may be safely employed in these larger amounts, spinal fluid tests frequently yield positive reactions when the serum tests yield negative reactions.

As stated in Chapter XXXIX, tests employing single doses of serum may occasionally yield falsely negative reactions, because of the presence of some substance in serum tending to inhibit complement-fixation by "reagin" and antigen; with such sera, positive reactions occur with smaller amounts of serum. This phenomenon, however, has not been observed with spinal fluids and it is far safer, therefore, to use single large doses of spinal fluid in conducting complement-fixation tests than single large doses of serum. A quantitative test, however, employing varying amounts of spinal fluid, is to be preferred, as yielding reactions of greater value for estimating the degree of complement fixation. For this reason I employ five different amounts of fluid ranging from 0.5 c.c. to 0.03 c.c. shown in Chart 5. The reactions are expressed as *negative*, if hemolysis is complete in all tubes; *weakly positive*, if fixation occurs in the first tube; *moderately positive*, if fixation occurs in the first two tubes; *strongly positive*, if fixation occurs in the first three tubes and *very strongly positive*, when fixation occurs in the first four or all five tubes. The degree of fixation in each tube may be expressed with the ++++, +++, ++, and + method as in the usual qualitative test; the method gives, therefore, a two-way quantitative reading as described with more detail in Chapter XXXIX.

Undoubtedly the complement-fixing antibody, or "reagin," is produced locally in the syphilitic foci in the central nervous system. Wassermann and Lange[23] have expressed the opinion that one source is the small lymphocytes. They have found that autolysis of these cells in spinal fluids from syphilitic cases increases complement fixation, whereas autolysis of the cellular elements in fluids from non-syphilitic cases (non-syphilitic meningitis and alcoholic dementia) did not produce these substances. It is highly probable, therefore, that in some cases of neurosyphilis the "reagin" content of the spinal fluid is higher than of the serum, but, since spinal fluid is being rapidly absorbed, I believe the occurrence of positive reactions with cerebrospinal fluid with negative serum reactions are largely to be explained on the fact that larger amounts of the former may be employed in the tests.

A question of great practical significance, however, is whether "reagin" in the blood may gain access to the spinal fluid. In other words, does a positive spinal fluid reaction indicate spirochetic infection of the central nervous system, or may it be due to the passive transfer of the "reagin" in the blood plasma produced elsewhere in the body? According to the experiments of Sekiguchi and myself,[24] it is apparently possible for syphilis "reagin" in the blood to appear in traces in the spinal fluid, because the spinal fluids of dogs tested three hours after the intravenous injection of 30 to 50 c.c. of human syphilitic serum per kilogram of weight sometimes yielded weakly positive reactions. After the intraspinal injection of an irritant as sterile horse serum, the amount of "reagin" in the spinal fluid was somewhat greater. A positive complement-fixation reaction with spinal fluid, showing no increase of cells and no increase of protein, or but a trace, may be due to a passive transfer of reagin in cases presenting strongly positive serum reactions; but in the great majority of cases the positive complement-fixation reaction is accompanied by at least a slight increase of cells and protein and is to be interpreted as indicating spirochetic invasion and infection of the tissues of the central nervous system.

When the spinal fluid is tested during the primary and early secondary stages of syphilis, the complement-fixation reactions are frequently negative when the cells and protein are slightly increased. This indicates that spirochetic invasion first brings about an increase of cells and protein, but that more time is required for the production of sufficient "reagin" to yield positive reactions.

As with serum tests, the specificity and sensitiveness of the technic are of primary importance in examinations of spinal fluid. With my new method, the reactions are frequently positive before the colloidal gold and mastic tests yield positive reactions, and I believe the complement-fixation test is the most reliable single test for syphilis of the central nervous system and especially with spinal fluids containing traces of blood, which render cell counts, protein determinations and the colloidal gold reactions unreliable or worthless. In other words, a trace of blood in spinal fluid does not interfere with the complement-fixation reaction, and under acceptable technical conditions it is diagnostic of syphilis, at least in this country, where frambesia (yaws) and trypanosomiasis do not occur, these being the only two non-syphilitic diseases capable of producing positive reactions.

Variations in Serum- and Spinal-fluid Complement-fixation Reactions.—In neurosyphilis the blood serum and spinal fluid Wassermann reactions may present varying results which are of considerable importance in relation to diagnosis and treatment and frequently troublesome from the standpoint of proper interpretation. Four combinations may occur as follows:

Both positive.
Both negative.
Blood serum, positive; spinal fluid, negative.
Blood serum, negative; spinal fluid, positive.

As would be expected, the percentages of the four groups observed by different investigators have varied considerably according to the stage of syphilis, the treatment given and especially the sensitiveness of the complement-fixation method.

As previously stated, I believe that the differences are sometimes due to technical factors and that we are better able to detect traces of complement-fixing "reagin" in the spinal fluid than in the serum, because we may safely use in our tests at least five times more of the former than of the latter, thereby accounting for some of the cases in which the blood serum reaction is negative and the spinal fluid positive.

Both Blood-serum and Spinal-fluid Reactions Positive.—In untreated early syphilis the blood reactions are positive in 85 to 100 per cent. of cases, but the spinal-fluid reactions are positive in but 30 to 40 per cent. In treated cases of early syphilis, the blood-serum reactions are positive in from 80 to 90 per cent. and the spinal-fluid reactions in 20 to 30 per cent. Both are positive, therefore, in but 20 to 40 per cent. of cases of early syphilis. This variation in blood- and spinal-fluid reactions in early syphilis is due to the fact that in the tissues of the central nervous system spirochetic infection has not occurred or is too early or too light to produce in the spinal fluid appreciable amounts of "reagin."

In late or chronic neurosyphilis syphilis, however, there is greater uniformity in the blood-serum and spinal-fluid reactions, because of the infection of the central nervous system; not infrequently, however, the blood serum reaction will be negative and the spinal-fluid positive, on account of the fact that "reagin" is being produced in larger amount in the nervous system and finding its way into the spinal fluid.

Both Blood-serum and Spinal-fluid Reactions Negative.—This combination is particularly influenced by the sensitiveness of the complement-fixation method. In untreated syphilis in the late primary stage, the blood serum may give a negative reaction in about 15 per cent. of cases with my method, and in these the spinal-fluid reactions are likewise invariably negative. In the secondary stage, however, the serum reactions are positive in almost 100 per cent. and the spinal-fluid reactions positive in about 40 per cent. In treated cases of early syphilis, about 10 to 20 per cent. may give negative reactions with both blood serum and spinal fluid. In chronic neurosyphilis however, it is very difficult to express percentages and I have not yet accumulated sufficient data with my new method upon which to express an opinion.

Blood Serum Positive and Spinal Fluid Negative.—This combination is particularly likely to occur in early cases of syphilis and especially in treated cases. For example, in cases examined within one year after infection and receiving no treatment, the blood-serum reactions are 85 to 100 per cent. positive and the spinal-fluid reactions 30 to 40 per cent. positive; in treated cases, the serum reactions are 80 to 90 per cent. positive and the spinal-fluid reactions 20 to 30 per cent. positive.

In chronic neurosyphilis, however, the blood serum is seldom positive with negative spinal-fluid reactions, provided large amounts of spinal fluid are employed. If relatively small amounts of spinal fluid are tested, the proportion of positive serum reactions will be considerably higher and especially in tabes dorsalis. But if the proportions of serum and spinal fluid employed in the tests are 1:5 or 1:10, not more than 10 per cent. of cases of chronic neurosyphilis will yield a positive serum and negative spinal-fluid reaction.

Blood Serum Negative; Spinal Fluid Positive.—This group is of special interest and importance in neurosyphilis and particularly in cases of syphilis receiving treatment. As a general rule, the spinal fluid is not examined until the blood serum reactions have been rendered negative by treatment; but in about 15 to 25 per cent. of cases of syphilis in which treatment is given and negative blood-serum reactions are observed within the first eighteen months after infection, the spinal-fluid reactions will be found positive and an indication for further specific treatment. Of course, the percentage of such cases varies with the kind of treatment given in the early stages of syphilis, but the possibility of their occurrence constitutes a demand for at least one examination of spinal fluid after the first year or eighteen months of treatment, to guard against the very regrettable error of discharging a patient as cured on the basis of even a series of negative blood-serum reactions. And there is no reliable clinical substitute for spinal fluid examinations, as such cases may present absolutely no neurological signs or symptoms; not even pupillary changes.

Lange Colloidal Gold Reaction with Cerebrospinal Fluid in Syphilis.—The colloidal gold or gold sol reaction with cerebrospinal fluid is one of the most valuable tests available for neurosyphilis. Unfortunately, however, its reactions are not specific for syphilis and may occur in some non-syphilitic diseases associated with meningitis or parenchymatous changes with nerve tissue destruction. But in the majority of cases of syphilis, the possible presence of these disturbing factors are readily eliminated and under these conditions the colloidal gold test serves as a sensitive detector of neurosyphilis and the kind or degree of reaction furnishes an index of the degree of infection. One distinct disadvantage of the Lange colloidal gold reaction, however, is the difficulty of preparing the reagent. If this is too sensitive falsely positive reactions may occur; if the colloidal gold is too greatly protected, the reagent is not sufficiently sensitive and yields falsely negative reactions. I have repeatedly sent specimens of the same spinal fluid to three different laboratories and obtained widely varying reports. We are urgently in need of a standardized method for preparing the reagent, so that different lots prepared at different times may yield closely similar results. Until such is available, I believe it is hardly worth while employing the colloidal gold test as a guide in treatment, because with different reagents in apparently perfect physical condition one may obtain widely varying results with the same spinal fluid. The presence of blood in spinal fluid also opens up an avenue for error in this test which is absent in the complement-fixation test.

With an acceptable reagent, however, the colloidal gold test is very valuable and should not be omitted in the routine examination of spinal fluid for syphilis. As shown in Chart 5, ten dilutions are employed prepared with 0.4 per cent. saline solution and the technic of setting up the tests is extremely simple. The reagent has a deep red color and, when this is unchanged, the reaction is expressed with a cipher, so that a line of ten ciphers (0000000000) indicates a negative reaction. The first evidence of precipitation is indicated by a change in color to red-blue indicated by 1 and from this to complete precipitation, indicated by 5, there is a range of colors as listed in Chart 5. In paresis the precipitation is usually complete in the first three to six tubes, giving a color reaction something like 5555321000; this type of curve is designated as the "paretic curve" or Zone I reaction. In tabes the color changes are usually somewhat as follows: 0135521000 designated as the "tabetic curve," "leutic zone reaction" or Zone II reaction.

Unfortunately, however, these types of reactions are not pathognomonic. The "paretic curve" is generally found in paresis or in the pre-paretic stage of neurosyphilis, but may occur in syphilitic meningitis (cerebrospinal syphilis) and even in early asymptomatic neurosyphilis as reported by Moore.[25] As shown by Fordyce, however, a "leutic zone" or Zone II reaction constitutes very reliable evidence against the presence of paresis and in this manner the colloidal-gold reaction is frequently of great value in differential diagnosis. Fordyce, Wile and others, have sometimes observed Zone I or "paretic curves" many months before the development of even the early clinical symptoms of paresis, and the reaction may give, therefore, warning of the threatened onset of this dreaded disease and indicate thereby the necessity of vigorous treatment. This type of curve is always diagnostic of syphilis and is always to be interpreted as of very grave prognostic significance. Individuals whose spinal fluid yields a reaction of this kind are to be carefully watched for paretic symptoms and signs, and should receive intensive treatment; this curve is usually associated with an increase of cells and protein and strongly positive complement reactions, and, as stated above, these are invariably grave cases of neurosyphilis, apt to be "Wassermann-fast" and demanding the utmost vigilance and diligence in treatment.

The second type of curve, the so-called "luetic," "tabetic" or Zone II reaction, indicates the presence of neurosyphilis, but bears no constant relation to the signs and symptoms. It is usually found in asymptomatic cases and indicates the presence of syphilis in just the same manner as a positive Wassermann reaction; while the "paretic" or Zone I reaction is highly diagnostic of syphilis, this so-called "luetic" or Zone II reaction may occur in non-syphilitic diseases of the central nervous system and, when the spinal fluid yields a negative complement-fixation reaction and is otherwise approximately normal, the reaction has little or no significance.

In syphilis this type of curve has a much better prognostic import than the "paretic" or Zone I curve. Such patients are not as heavily infected, are not apt to be "Wassermann-fast" and respond more promptly to treatment. The outlook for the patient is always more favorable than when the spinal fluid yields a "paretic" or Zone I reaction.

Time of Invasion of the Central Nervous System with Spirochæta Pallida. There is little or no doubt that in practically all untreated cases of syphilis in the primary and secondary stages, the tissues of the central nervous svstem are invaded with *Spirochæta pallida* during the initial spirochetemia; evidences are found in the spinal fluids of approximately 60 per cent., but in the balance it is highly probable that invasion has occurred without the production of symptoms or spinal-fluid changes.

The question now arises, may invasion occur at subsequent times? If the spinal fluid is found normal one or two years after infection of cases receiving none or insufficient treatment, does this guarantee that the central nervous system is free of infection and will remain free? Unquestionably infection of the central nervous system is successfully combated by some patients who are insufficiently treated or not treated at all; but does this initial escape protect against subsequent infection? Most writers have expressed the opinion that if the spinal fluid shows no abnormalities at the end of the first or second years after infection, that neurosyphilis is not likely to develop at a subsequent time; indeed, some have stated that if the spinal fluid is found normal after the first or second courses of treatment, that neural infection will not subsequently occur and that further spinal-fluid examinations are not required. Wile and Marshall[26] believe that any patient whose spinal fluid is found normal after the secondary eruption has developed is

not likely to subsequently show abnormal changes; Stokes and McFarland[27] observed only four cases in a series of 114 who developed abnormal spinal-fluid changes after preceding negative examinations, and Finger and Kryle[28] have likewise stated that while there is no relation between the degree of cutaneous exanthems and percentage of meningeal invasions, yet negative spinal-fluid examinations at the end of the secondary period of syphilis tells the story and that a reversal to abnormal changes in the later stages is rare. As stated by Stokes and McFarland, "the syphilographer who carries the treatment of his primary and secondary cases into their second course without examination of the spinal fluid is proceeding blindfolded."

I believe it is true that, if the spinal fluid is found normal at the end of the first year of treatment, the patient can be greatly assured that the danger of neurosyphilis is past, but this certainly is not true after but one or two courses of treatment. Even after one and two years of treatment, complete cure may not be effected and there is always danger of temporary periods of spirochetemia with invasion and possible infection of the central nervous system. Experience has taught me in common with others that the greatest danger of neural infection is during the early stages of syphilis, that is, during the first six to twelve months after infection, but as long as the blood Wassermann reaction is positive or other signs of uncured syphilis are present, I believe that the danger of development of neurosyphilis exists. For this reason a negative spinal fluid examination with a positive blood Wassermann reaction does not assure against the possibility of subsequent neural infection; only when a negative spinal-fluid examination follows a series of negative Wassermann reactions over a period of one or preferably two years, may we feel reasonably assured that neurosyphilis will not subsequently develop. For this reason I routinely advise spinal puncture after the first six months or year of treatment to be followed by at least one more examination after the blood complement-fixation reaction has been persistently negative for one or two years.

Influence of Chemotherapy upon Cerebrospinal-fluid Changes in Early Syphilis.—The very important influence of specific treatment in the early stages of syphilis on the cerebrospinal-fluid abnormalities and clinical manifestations of neural infection has been brought out in a clear and convincing manner by the investigations of Fordyce and Rosen, Wile, Stokes and McFarland, Keidel, Moore and others mentioned above. Of course, the findings of these investigators have varied considerably and especially because the amount and kind of treatment given the respective group of patients have varied, but there is a uniformity of opinion in support of the statement that after three or more courses of treatment, each course embracing not less than four to six injections of arsphenamin or neoarsphenamin at weekly intervals followed by four to six weeks of mercury by injection or inunction, the incidence of abnormal spinal fluid findings is reduced almost one half. For example, in primary syphilis, the incidence is reduced from 20 to approximately 12 per cent. by arsphenamin treatment and in secondary syphilis, from 40 to 60 per cent. to approximately 25 to 35 per cent. According to Stokes and McFarland, the percentage of abnormal spinal fluids among cases of early syphilis may be reduced from 60 to 70 per cent. to 40 per cent. within the first six months, and to 25 or 30 per cent. after the first year or two, the decline being more gradual from this time.

As shown by Keidel and Moore,[29] treatment must be continuous over a comparatively long period of time to exert these effects. A few injections of arsphenamin or neoarsphenamin with or without mercury, accomplishes but little. As shown by Moore, the incidence of 29.8 per cent. of neurosyphilis

in one group with little treatment was reduced to 13.1 per cent., in a second group treated with eighteen doses of arsphenamin plus mercury, and to 8.0 per cent. in a third group treated with twenty-four or more doses of arsphenamin plus mercury. A decrease in cells is usually the first sign of improvement followed by a decrease of protein, a reduction in the degree of complement-fixation and finally a reduction in the degree of colloidal gold precipitation. The last mentioned reaction is the last to disappear, and in my experience, fluids showing the "paretic" or Zone I type of reaction are seldom influenced to any marked degree except in some cases treated by malarial inoculation.

But the response to treatment varies considerably among different cases of early neurosyphilitics. For example, among those presenting no symptoms but showing an increase of cells and protein with negative complement-fixation and colloidal gold reactions, the response is far more marked than among those showing some symptoms, pleocytosis, increase of protein and positive complement-fixation and colloidal gold reactions; indeed, among this group four courses of treatment may have little or no effect upon the Wassermann and gold reactions, although symptoms disappear and the pleocytosis and protein content decrease to normal or approximately normal proportions. Furthermore, as a result of treatment, the spinal-fluid changes may be temporarily increased, probably as a result of producing neuro-recurrences which I shall discuss shortly with more detail, but producing no signs or symptoms of such, because, as suggested by Gennerich,[30] the lesion is in a "silent area" not involving cranial nerves or other important tissues.

While these results show the very considerable importance of active and continuous specific medication in the early stages of syphilis for the prophylaxis and cure of neural invasion and infection, actual harm may be done by insufficient treatment. Moore has shown, for example, that, when treatment in early syphilis voluntarily ceased or "lapsed" after one to twelve doses of arsphenamin, either with or without mercury, and the spinal fluid was examined weeks or months later, the incidence of abnormal spinal fluids was three times higher than under regular treatment. Furthermore, as a result of lapsed treatment, the percentage of cases showing the advanced spinal-fluid changes of high pleocytosis, increase of protein and positive complement-fixation and colloidal gold reactions with slight symptoms, became twelve times higher than a similar group under regular treatment.

Irregular treatment, therefore, may be even worse than no treatment at all, insofar as invasion and infection of the central nervous system is concerned, because the incidence of infection may be actually higher than when no treatment at all has been given. The reasons for this are probably the same as advanced for explaining the mechanism of neuro-recurrences under arsphenamin treatment, which are briefly discussed in the succeeding section.

Influence of Chemotherapy upon the Production of Neuro-recurrences.—Soon after the introduction of salvarsan for the treatment of syphilis, it was noticed that not infrequently precocious clinical neurosyphilis followed the administration of one or several doses. The subject naturally excited a great deal of discussion as regards the nature and mechanism of the reaction and for a while it was regarded as a toxic effect of salvarsan upon nerve tissue or an expression of neurotropism of this substance. But it is now definitely known to be due to *Spirochæta pallida* and the tissue changes excited by this parasite, an excellent bibliography of the literature on the subject prior to 1912 being given by Ellis[31] along with the report of a case developing during the secondary stage of syphilis.

Almost without exception neuro-recurrences (neuro-recidives) develop as a result of lapses in treatment after a few doses of arsphenamin or neoarsphenamin. Ehrlich[32] believed that, under these conditions, when arsphenamin treatment fell short of complete sterilization, spirochetes survived in isolated foci and became even more active than usual because the treatment given not only failed to sterilize but reduced the development of resistance or immunity by the patient. In these foci the surviving spirochetes produce an intense lymphoid infiltration and, if they happen to be situated in physiologically important tissues as one or more of the cranial nerves, marked signs and symptoms develop; on the other hand, if the foci are situated in the "silent areas" or physiologically unimportant tissues, signs and symptoms of these neuro-recurrences may not be apparent.

As a general rule, the lesions of neuro-recurrences develop rather slowly and occur weeks or months after the interruption of specific medication with arsphenamin, neoarsphenamin or mercury. In this respect they differ from Jarisch-Herxheimer reactions. The latter usually develop in a matter of hours or a few days after an injection of arsphenamin or neoarsphenamin and are expressed by an exacerbation of lesions or symptoms already present; neuro-recurrences, however, are new lesions developing slowly rather than the sudden accentuation of present lesions. Neuro-recurrences are due to the renewed activity of spirochetes in a host who has not been able to develop sufficient immunity; Herxheimer reactions suggest rather a reaction between medicament and syphilitic tissue, although they may be due to renewed spirochetic activity or result in the stimulation of spirochetes.

Spinal fluid changes generally occur upon the development of a neuro-recurrence and especially an increase of the cells, but this pleocytosis does not necessarily indicate a diffuse meningeal reaction, but may result from one or several focal lesions. Diagnosis is largely based upon clinical signs and symptoms and usually offers no difficulties.

From the standpoint of chemotherapy, emphasis is to be laid upon the value of continuous treatment of early syphilis for the prophylaxis of neuro-recurrences; treatment of the nerve lesions themselves is considered in Chapter LXXVI. Some physicians hesitate to administer arsphenamin and neoarsphenamin in the *early stages* of syphilis believing that the development of immunity is thereby retarded; mercury is first administered followed by arsphenamin or neoarsphenamin. However, if treatment is vigorous and continuous after the plan described in Chapter LXXI, the danger of neuro-recurrences or precocious neurosyphilis is reduced to a negligible minimum as the spirochetes are rapidly destroyed; I believe it is a dangerous principle to rely too much upon the development of immunity for the aid it may render in protecting tissues and organs. Rather it is advisable to destroy the spirochetes as promptly as possible if the general condition of the individual case permits of the vigorous administration of arsphenamin or neoarsphenamin followed by mercury.

Others prefer starting the treatment of *chronic* syphilis with mercury in order to avoid sudden stimulation of spirochetes with the more powerful arsenical preparations; I believe this is a good practice, as discussed in Chapter LXXIV.

Spinal Fluid Changes in Chronic Syphilis and the Influence of Chemotherapy upon These.—In chronic latent and active syphilis, changes in the cerebrospinal fluid are usually to be found but not always; for this reason a normal spinal fluid may be found in the presence of neural infection, but the lesion or lesions are likely to be vascular, small, inactive and asymptomatic. In this connection may be mentioned the studies of Solomon and Klauder[33]

upon the negative spinal fluid findings in cases of neurosyphilis and especially those with vascular lesions; likewise the report of Southard and Solomon[34] of negative spinal-fluid findings in cases presenting clinical symptoms and signs of paresis, "paresis sine paresi," and the report of Wynn[35] concerning the disappearance of spinal-fluid findings in a case of paresis although with a continuation of symptoms. Mention may be made also, at this time, of the report of Solomon and Klauder,[36] indicating that the intravenous or intraspinal injection of arsphenamin may provoke positive spinal-fluid changes in cases previously negative.

Not infrequently only a slight increase of protein and a slight increase of cells are the only abnormalities found in the spinal fluid, and these are frequently over looked or under rated and ascribed to technical inaccuracies. Their occurrence emphasizes anew the necessity for accuracy in the conduct of spinal fluid examinations, so that due notice and emphasis may be placed upon even the slight abnormal changes.

Can spirochetes be present in the tissues of the central nervous system without producing symptoms, changes in the spinal fluid or positive blood Wassermann reactions? This very important question of course bears a relation to the question of complete cure of syphilis and cannot be answered at the present time on the basis of proven facts. At least one or more decades must pass during which we may watch and study patients with all these present-day criteria of "cure" to determine if cure has been absolute. I am prepared to believe, however, that it is possible for spirochetes to be so reduced in numbers and activity as to remain quiescent in the neural tissues without the production of spinal fluid and other changes, as Warthin has apparently shown may occur in the myocardium and other internal organs. But I am quite sure that under these circumstances "cure" may be said to exist, insofar as general health and usefulness are concerned, and that active lesions usually produce sufficient changes in the spinal fluid to indicate their presence even though symptoms are not produced, or are light and atypical.

As would be expected, the spinal-fluid changes in chronic syphilis vary considerably in different patients according to the size, location and activity of the lesions. Even among individuals presenting the same symptom-complexes and suffering presumably with the same kind of lesions, the spinal fluid changes may vary, but I cannot devote space to a consideration of these, since my purpose is to deal mainly with the treatment rather than the diagnosis of syphilis. From the standpoint of "typical" changes in the spinal fluid, probably Chart 6 may prove of some aid in diagnosis, in which the changes have been arranged according to the anatomical and clinical classification of neurosyphilis given on page 536.

I have not recorded in this chart the findings in syphilitic psychoses, because relatively few have come under my observation; Fordyce states that the spinal fluid is usually normal. A word may be said, however, regarding these cases. Due care must be exercised against including cases of "syphilophobia" in this group; also that relatively large number of syphilitics with what Collins[37] has so aptly expressed as having "syphilitic scars of the spirit." Many cases of syphilis develop this pessimism regarding cure and ascribe every ache and pain to syphilis regardless of how ridiculous their fears are in many instances. Such a condition may develop into a psychosis, but I reserve the term for those mental states sometimes developing in tabes and other forms of neurosyphilis which may have an actual organic basis.

Under the influence of specific medication, the cerebrospinal-fluid changes are modified in some cases, while in others no change occurs or they increase in severity. Owing to the pain and discomfort of spinal puncture and par-

CHART 6.—CHART SHOWING TYPICAL LABORATORY FINDINGS IN NEUROSYPHILIS

DIAGNOSIS	CEREBROSPINAL-FLUID CHANGES					POSITIVE BLOOD WASSERMANN REACTIONS, PER CENT.
	PRESSURE	TOTAL CELLS	PROTEIN	POSITIVE WASSERMANN REACTIONS, PER CENT.	POSITIVE COLLOIDAL GOLD REACTIONS,* PER CENT.	
Early† asymptomatic, untreated	Not increased	2–150	+ to +++	30– 40	15 Zones I and II	85–100§
Early asymptomatic, treated	Not increased	0– 100	+ to ++	20– 30	12 Zones I and II	80– 90
Early acute meningitis	Increased	100–1000	++++	100	100 Usually Zone I	100
Chronic‡ latent asymptomatic	Not increased	0– 20	− to +	60– 80	60–80 Usually Zone II	50– 80
Chronic diffuse meningitis (cerebrospinal syphilis)	Increased	5– 500	+ to ++++	90–100	90–100 Usually Zone I	60– 80
Chronic localized meningitis	Not increased	0– 40	+ to ++	80– 95	80– 90 Usually Zone II	80– 95
Paresis	Increased	10– 300	++ to ++++	100	100 Usually Zone I	95–100
Tabes dorsalis	Usually not increased	20– 200	+ to ++	90– 95	90–100 Usually Zone II	80– 90
Tabo-paresis	Increased	10– 200	+ to +++	90–100	90–100 Usually Zone I	90–100
Erb's spastic spinal palsy	Not increased	5– 50	+ to ++	80– 90	80– 90 Usually Zone II	80– 90

* Zone I refers to the "paretic" type of curve (example: 5553210000); Zone II refers to the "luetic" zone curve (example, 0134420000).
† "Early" refers to cases examined within 12 to 18 months after infection.
‡ "Chronic" refers to cases examined 1½ years or longer after infection.
§ Eighty-five per cent. positive Kolmer complement-fixation reactions in late primary stage; 100 per cent. positive in secondary stage.

ticularly the chances of developing spinal puncture headache, we are not usually able to conduct more than one to three spinal punctures unless a form of intraspinal treatment is being employed.

Apparently the first sign of improvement is a decrease in cells, although, if spinal injections are being given, the cells may be temporarily increased due to meningeal irritation. The next change is a decrease in proteins accompanied by a reduction in the degree of complement fixation. The last change to be affected is the colloidal gold reaction and it is usually the last abnormality to disappear. Zone II reactions are more readily influenced than Zone I and may be eradicated altogether. Zone I reactions ("paretic curves") may be converted in to Zone II reactions ("leutic zone curves"), but in my experience are rarely eradicated altogether by medicinal treatment although sometimes disappearing under treatment by malarial inoculation.

PART VIII

PHARMACOLOGY AND TOXICOLOGY OF ANTISYPHILITIC MEDICAMENTS

CHAPTER XLIII

PHARMACOLOGY OF ARSPHENAMIN, NEOARSPHENAMIN AND ALLIED DRUGS IN RELATION TO METHODS OF ADMINISTRATION AND THE TREATMENT OF SYPHILIS

Since syphilis of human beings is predominently an infection of the fixed tissues rather than of the body fluids, it is required as a principle of treatment that the chosen remedy shall be present in adequate amounts and in an *active* spirocheticidal state over relatively long periods of time with a minimum degree of toxic effects. In the very earliest stages of syphilis medicaments may readily reach and destroy the spirochetes in the tissues and lymph spaces of the chancre and likewise those organisms already in the lymph, lymphatic glands and blood; but after dissemination has become widespread, with lymphocytic and fibrous tissue infiltrations about the foci of spirochetes, the matter of penetrability of these inflammatory exudates by the organic arsenical, mercurial or bismuth compound chosen for treatment, requires careful consideration. In this relation the size of the dose, frequency and route of administration are of primary importance in which clinical experience and a knowledge of the results of animal experiments for curative and toxicological effects, absorption, distribution and elimination of the drug, is required in the interests of best therapeutic management and especially in the chronic stages of the disease. The rapidity of absorption of the drug is important in relation to the question of prolonged therapeutic activity; for this reason it has long been recognized that a therapeutically active organic arsenical compound which may be administered by subcutaneous or intramuscular injection would have a very useful place in the treatment of chronic syphilis, and sulpharsphenamin (sulfarsenol) has been recently advocated for this purpose. Rapidity of elimination is likewise a factor of importance, but with the organic arsenicals this refers more to the elimination of the therapeutically active oxidation products of the arsenobenzol compounds than to the elimination of the inorganic arsenic in the form of arsenites and arsenates. In other words, the rapidity of elimination of the therapeutically active "oxids" of the organic arsenical compounds and the pentavalent arsenicals bear an important relation to the degree and duration of therapeutic activity, while elimination of the arsenic of these compounds in inorganic form is of lesser interest because these arsenites and arsenates possess little or no therapeutic activity. However, the elimination of these bears an important relation to the question of toxicological effects.

For these and other reasons studies bearing upon the absorption, distribution, retention and elimination of arsenical, mercurial, bismuth and

iodin compounds have an important practical relation to the question of maintaining the medication in the body fluids at the point of maximum therapeutic activity with the minimum toxicological effects for sufficient periods of time to bring about the destruction of *Spirochæta pallida* in the blood, lymph and fixed tissues; in this chapter it is proposed to discuss these phases of the pharmacology of the organic arsenical compounds in relation to the methods of administration and the treatment of syphilis.

Importance of Analytical Methods and of "Normal" Arsenic in Tissues and Excretions.—Owing to the great interest for centuries in arsenic from the toxicological standpoint, numerous methods have been devised for its quantitative estimation in the tissues and excretions. Soon after the discovery of salvarsan and its use in the treatment of syphilis, untoward effects stimulated renewed interest in the question of the fate of the drug after intramuscular and intravenous injection with particular reference to the elimination and retention of arsenic. Abelin[1] devised a method for the detection of arsphenamin and its substitutes in the blood, urine, etc., but most investigators have employed methods for the qualitative and quantitative estimations of inorganic arsenic. To-day considerable difference of opinion exists among chemists regarding the sensitiveness and comparative value of these methods; probably the Reinsch, Marsh and Gutzeit methods or modifications of these have been mostly employed, although within recent years the Gutzeit, Marsh-Berzelins and the Green iodometric methods appear to have been proven especially reliable and popular.

From the standpoint of arsenic determinations in the excreta and tissues, the question of the presence of this element "normally" has commanded considerable attention, since Gautier[2] in 1899 asserted that arsenic is a normal and consistent constituent of the thyroid, thymus and mammary glands, blood, brain, skin, bones, hair and milk of man and various animals. The quantities found were very small, being less than 0.75 mg. for each hundred grams of tissue and the content of the blood not exceeding one part in fifty millions. These observations were soon confirmed by Bertrand,[3] Schaefer,[4] Knecht and Deardon[5] and others, and in 1903 Gautier and Clausmann[6] found traces of arsenic in a variety of foods such as meats, milk, eggs, fish, vegetables, wines, etc., from which they estimated that each inhabitant of Paris receives about 7.66 mg. arsenic per year in his food. Bloemendal,[7] Bang[8] and Klason[9] have found arsenic in normal urine, and the sum total of these investigations have shown the great importance of taking into consideration the possibilities of this so-called "normal or physiological" arsenic not only in medico-legal determinations, but also in studies concerning the fate of arsenic after the administration of arsenical compounds.

Within the last year Fordyce, Rosen and Myers,[10] employing a modification of the Marsh test,[11] have studied this question of "normal" arsenic with particular care in a series of valuable investigations concerning the fate of arsphenamin and allied drugs employed in the treatment of syphilis. An examination of the blood, urine, hair and milk from about 200 persons has led to the conservatively made statement that arsenic is found "normally" in a large number of persons, depending upon the character of their food, drink, medication and environment. Under conditions of diet restricted in the amount of sweets, vegetables, meat, etc., it may be entirely absent. Some persons did not give a positive test at all times. Arsenic was almost invariably present, in different amounts, in persons applying remedies containing ingredients contaminated with it to inflamed or ulcerating skin surfaces, and to a greater extent in persons receiving the element either by mouth or intravenously, or connected with arsenicals in a preparative way. At any rate, this latest analytic data, including such simple, every-day items as rhubarb and soda, sulphur ointment and sulpho-ichthyolate preparations, as well as foods, in the list of "carriers" of arsenic, show that a careful history of the patient is requisite before arriving at a final decision regarding the meaning of the arsenic content of the blood, urine or internal organs.

Absorption of Arsphenamin, Neoarsphenamin and Sulpharsphenamin in Relation to Methods of Administration.—When antisyphilitic drugs are administered by intravenous injection, the question of absorption is of little importance, because the medicaments are thrown into the blood in solution and in the case of the arsphenobenzene compounds may exert parasiticidal effects in a matter of thirty minutes or less. One disadvantage of intravenous

medication, however, is rapidity of elimination and consequently short periods of spirocheticidal activity; likewise toxic effects are more likely to occur.

The rate of absorption after subcutaneous and intramuscular injection, or after administration by mouth or by rectum, is readily determined by chemical analysis of the blood and excreta. In the case of arsphenamin, neoarsphenamin, sulpharsphenamin and allied drugs, examinations of this kind are usually confined to analyses for inorganic arsenic, although direct tests for arsphenamin itself have been applied by means of the Abelin method or some modification of it. The rate and degree of absorption can also be studied biologically, that is to say, by infecting lower animals with trypanosomes or spirochetes at varying intervals after the administration of the drugs. This method has the added advantage of indicating not only the time required for the absorption of the drug, but, furthermore, whether or not the drug has been absorbed in an active parasiticidal condition. The "therapeutic test" is likewise a sort of index of absorption of therapeutically active compounds in the treatment of syphilis of human subjects presenting external lesions that may be carefully watched for regressive changes.

The absorption of antisyphilitic drugs is a question of considerable practical inportance not only in relation to the rapidity but also to the prolongation of curative activity. As we shall shortly review, the rapidity of absorption is influenced by many factors requiring due consideration among which the degree of local inflammatory reaction about the sites of subcutaneous and intramuscular injection, the solubility of the drug, the menstrum employed for suspensions, etc., are the most important.

Absorption after Intramuscular Injection.—The rate of absorption from the muscles depends primarily upon the degree of injury produced; neoarsphenamin, for example, produces much less irritation than arsphenamin and is absorbed almost five to six times more quickly. Some brands of sulpharsphenamin are absorbed even more rapidly. Swift[12] has found that in rabbits injected intramuscularly with arsphenamin in alkaline solution, in neutral suspension and in oily suspension, only about 30 to 40 per cent. absorption of arsenic occurs during the first week, about 50 per cent. during two weeks and that as much as 20 per cent. may still be found in the muscles at the end of six weeks. The rate of absorption was most constant after the injection of neutral suspensions, a little more irregular after the injection of the alkaline solution, and most irregular after the injection of the acid suspension, the results appearing to bear a ratio to the degree of local irritation. The effect of concentration was much less constant. About 80 per cent. of the arsenic of *neoarsphenamin* was absorbed during the first week and 90 per cent. during the first two weeks, about 5 per cent. remaining at the end of six weeks.

Very little data is available at present upon the rate of absorption of *sulpharsphenamin* from the muscles and subcutaneous tissues. My own experiments have been conducted with sulpharsphenamin injected into the thigh muscles of rabbits in doses of 0.1 gm. dissolved in 1 c.c. of sterile distilled water. Analyses and histological sections of the excised muscles were made twenty-four, forty-eight and seventy-two hours later; the Abelin reaction and a modification described by Kolls and Youmans[13] for arsphenamin in the tissues were conducted, as well as total arsenic determinations. The results were quite irregular and varied considerably with two different brands of sulpharsphenamin; the degrees of local irritation varied likewise as discussed in Chapter XLVIII.

As a general rule, the Abelin reactions were positive with muscles excised at the end of twenty-four hours and the determinations for inorganic arsenic showed from 40 to 60 per cent. absorption. At the end of forty-eight hours

the Abelin reactions were generally negative, with from 50 to 80 per cent. absorption; at the end of seventy-two hours the Abelin reactions were negative, with about 90 per cent. absorption of the arsenic. As compared with intramuscular injections of neoarsphenamin in the same dose and concentration per kilogram of weight, the absorption of sulpharsphenamin was generally, but not always, considerably more rapid and likewise produced less tissue injury.

Absorption after Oral and Rectal Administration.—That arsphenamin is absorbed when administered orally was shown by Schamberg and myself[14] in 1912 and since then our observations have been confirmed by others. Arsphenamin and neoarsphenamin have also been administered by rectal injection by some physicians in the treatment of syphilis. Both suppositories and enemeta have been given. Undoubtedly, some absorption occurs after the administration of large doses to human subjects, as shown by curative effects upon syphilitic lesions, but the amount of absorption is somewhat less than follows oral administration and very much less than after intramuscular injection. In my experiments the rectal administration of rabbits with 0.050 gm. arsphenamin per kilogram of body weight in alkaline solution and similar doses of the powder itself in suppositories, did not produce any demonstrable degrees of irritation and traces of arsenic were found in the urine and bile within twenty-four hours, but the amounts were minute and usually none was found after seventy-two hours. Noeggerath and Reichle[15] have studied the absorption of neoarsphenamin after rectal administration to children in doses of 0.6 gm., by applying tests with the urine for the formaldehyd component; only traces could be found, while tests for arsenic in the urine were uniformly negative.

Absorption in Relation to Therapeutic Activity.—As previously stated, the absorption of these organic arsenical compounds may be studied also by biological methods consisting of administering the compounds to rats and infecting them at intervals with trypanosomes for determining the degree of absorption of therapeutically active amounts of drug, according to the curative influence exerted upon the course of the infection, or by administering the drugs to rabbits followed by testicular inoculation with *Spirochæta pallida.* Much more decisive information may be gained, however, in experiments employing rats infected with *Tr. equiperdum,* and the results are directly applicable to the effects produced in *Sp. pallida* infections. In my experiments upon this subject, white rats were infected by intraperitoneal injections of 500,000 *Tr. equiperdum* and twenty-four hours later treated with arsphenamin, neoarsphenamin and sulpharsphenamin by intravenous and intramuscular injection, oral and rectal injection; the results summarized as follows show the single minimal curative doses of various compounds by the four different routes of administration:

Drug	Minimal Curative Doses per Kilogram, by			
	Intravenous Injection	Intramuscular Injection	Oral Administration	Rectal Administration
Arsphenamin	0.004	0.004	0.028	0.045
Sulpharsphenamin	0.020	0.012	More than 0.030	More than 0.060
Neoarsphenamin	0.008	0.010	0.040	0.060

As shown in these experiments, the minimal curative doses of the three different drugs administered by intramuscular injection were practically the

same as by intravenous injection, but 6 to 10 times greater respectively, by oral and rectal administration. I think these results are particularly acceptable as practical indices of the relative therapeutic results to be expected from the organic arsenical compounds administered by these four different routes in the treatment of syphilis of human beings. It is particularly significant that the minimal curative doses of all three compounds by intramuscular injection were practically identical with the minimal curative doses by intravenous injection, in confirmation of the results observed by Voegtlin and Homer W. Smith.[16]

Distribution and Storage of Arsphenamin and Neoarsphenamin in Relation to Methods of Administration.—By whatever method the organic arsenical compounds are administered in the treatment of syphilis, distribution occurs principally in the blood. In intravenous medication, all of the drug administered is, of course, placed at once in the blood; but, as just stated above, arsenic determinations and biological tests have shown that, after intramuscular injections of arsphenamin, neoarsphenamin and sulpharsphenamin, almost as much therapeutically active compound finally reaches the blood by lymphatic and blood absorption as by intravenous injection. In other words, after subcutaneous and intramuscular injections, inflammatory reactions may delay absorption, but it does not appear that more than traces of the drug are fixed or absorbed by the tissues at the site of injection. Furthermore, it does not appear that the local tissues reduce the therapeutic activity of the medicament; indeed, in the case of the organic arsenical compounds, it is highly probable that the production of the active spirocheticidal compounds by oxidation or reduction, as the case may be, according to whether a trivalent or pentavalent compound has been injected, proceeds to some extent in the muscles before absorption and distribution.

After arsphenamin and neoarsphenamin reach the venous blood, they are carried to the heart and after passage through the lungs circulate, for a few hours at least, throughout all vascularized tissues of the body. Doubtless some is retained by the lungs and especially if intravascular precipitates have been produced; indeed, chemical analyses of the lungs of rabbits after intravenous injections usually show that a large amount of arsenic has been retained. Stuhmer,[17] for example, found that, after the intravenous injection of rabbits with acid solutions of salvarsan, most of the drug was to be found in the lungs. He thought that this indicated a special affinity of salvarsan for these tissues, but we now know that the effects were due to the production of precipitates of salvarsan in the blood which were filtered out in the capillaries of the lung. Concentrated alkalinized solutions of salvarsan (1 gm. in 25 c.c.) had a similar effect, whereas neosalvarsan was found to be more widely distributed. Stuhmer observed that neosalvarsan disappeared from the blood within twenty-four hours, whereas the acid and alkaline solutions were retained for as long as three days. He noted such large amounts of salvarsan in the intestinal contents that it was thought possible for oxidation to occur with the production and absorption of toxic substances. The lungs, liver and spleen were found to retain the largest amounts of both compounds, but subsequent investigations have shown that the compounds are not equally retained by the different organs and tissues.

In the first place arsphenamin and neoarsphenamin are distributed largely in the plasma and only a small amount is absorbed or fixed by the corpuscles; Barbat and Myers[18] for example, found more than five times as much arsenic in the blood serum as in the clots within half an hour after the intravenous injection of 0.4 gm. of salvarsan. Clausen and Jeans[19] employing a modification of Gutzeit's method for quantitative arsenic determinations, found

that little or no arsenic was present in the corpuscles after the intravenous injection of arsphenamin and that the serum contained as much as the plasma.

As I shall shortly discuss with more detail in a consideration of the elimination and retention of the organic arsenic compounds, arsphenamin and neoarsphenamin are apparently rapidly eliminated from the blood after intravenous administration. By means of the Abelin test for arsphenamin and its substitutes, examination of the blood may show none of the drug in circulation within one to three hours after injection, although, since arsphenamin may be found in the urine by this method for as long as twenty-four hours and since traces of arsenic may be found in the blood for a similar or even longer periods, it is likely that traces of arsphenamin, neoarsphenamin or their oxidation products may persist in the blood for periods beyond three hours.

It cannot be stated why arsphenamin, neoarsphenamin or other organic arsenical compounds circulating in the blood for brief periods, at least, and doubtless reaching all portions of the body by arterial distribution, are deposited or retained by some organs more than others. Doubtless this phase is controlled by physical factors as solubility, surface tension, electrical charge and various chemical reactions between cells and drug and varies with different medicaments. The concentration of a drug in the cells of an organ or tissue is dependent in part at least upon its concentration in the surrounding fluids, since it appears that simple diffusion follows the law of mass action. The problem is to bring up the concentration in one organ to an efficient threshold without involving other organs and this depends primarily upon the dose and rate of elimination; small divided doses, therefore, may not produce the same effects as single large ones, but organs containing the largest amounts do not always show more effects than those containing smaller amounts. In other words, the relative concentration in which a drug is present in different organs does not determine the extent to which these are involved in its action.

The arsenic of arsphenamin and neoarsphenamin has been found largely deposited in the lungs, liver and spleen; whether this denotes that these compounds themselves or their oxidation products have an affinity for these organs cannot be stated. It is probable and possible that arsenic is found in especially large amounts in the liver, not only because there is a special affinity between this organ and arsphenamin, but because the liver is an especially active organ of elimination of arsenic in general in the bile and the arsenic is doubtless brought to it for elimination from other organs and tissues. By a quantitative colorimetric modification of Abelin's method, Kolle and Youmans[20] found arsphenamin principally in the spleen, liver, lungs, heart and kidneys of a dog three hours after intravenous injection; only traces were found in the brain and none in the cerebrospinal fluid. Clausen and Jeans have found most arsenic in the liver, spleen and kidneys after intravenous injections. Bulmer[21] found, after the intravenous injection of rabbits with organic arsenical compounds in doses corresponding to those given to man, that the arsenic is found chiefly in the liver, lungs, kidneys and long bones. The important features in their distribution were: high concentration in the liver shortly after injection; rapid reduction of this concentration, presumably by the elimination of the arsenic in the bile; the relatively large amount in the lungs, especially after large doses, and the maintenance of a high arsenic content here over a period of at least several days, and its retention by the long bones over a longer period than that shown by any other tissue analysis. Voegtlin, Smith, Dyer and Thompson[22]

have also studied the distribution of arsenic in the organs of rabbits removed 100 and 200 minutes after the intravenous injection of arsphenamin, neoarsphenamin and other arsenical compounds and found largest amounts in the bile, urine, liver, spleen and stomach contents.

As previously stated, it is probable that the large amount of arsenic found in the liver and kidneys is due to the functional activity of these organs in the elimination of arsphenamin, neoarsphenamin or the inorganic arsenites and arsenates of these compounds, rather than to any special affinity between the compounds and these organs. The high arsenic content of the lungs is probably due to the retention in the capillaries of minute emboli of precipitated arsphenamin, even though there are no clinical signs or symptoms of embolism. Likewise, the high arsenic content of the heart muscle, in contrast to the low arsenic content of the skeletal muscles, may be due to the retention in the capillaries of the heart of very minute emboli of precipitated arsphenamin swept through the lungs and distributed by the coronary arteries. At any rate, these and similar studies have shown that, after the intravenous injection of arsphenamin, neoarsphenamin and allied compounds, widespread distribution of arsenic occurs, but that storage or retention varies greatly among the different organs. The same is doubtless true after intramuscular injections, although at any one time the amount of drug in the blood is much less. As stated by Voegtlin and Thompson, solubility, molecular weight, surface tension, electric charge and dissociation are probably important factors having a bearing upon the distribution of arsenical compounds in the body.

Penetration of Arsphenamin, Neoarsphenamin and Other Organic Arsenic Compounds in the Cerebrospinal Fluid and Tissues of the Central Nervous System.—Undoubtedly, after the injection of arsphenamin and allied compounds, the drugs circulate in the blood through the brain and spinal cord, but of special interest in this connection is the question of penetration to the cerebrospinal fluid in relation to the treatment of syphilis of these organs. The subject has excited a great deal of discussion and a great deal of investigation has been devoted to quantitative studies of the cerebrospinal fluid for arsenic in the form of arsenites and arsenates. Unfortunately the methods employed have not always been acceptable for the detection of minute traces of arsenic and, more particularly, have not always adequately controlled the possibility of errors due to "normal arsenic" in the spinal fluid and tissues from food, water and other sources and of arsenic in the reagents.

It is significant that only small amounts of arsenic have been found in the brain and spinal cord. McIntosh and Fildes[23] were unable to find any at all in the brain after the intravenous injection of arsphenamin and Rudolf and Bulmer[24] have more recently stated that after the intravenous and intraspinal injection of phenarsphenamin in rabbits, arsenic could not be demonstrated in the brain or spinal cord by the Gutzeit test. McIntosh and Fildes believed that the factor governing the passage of dyes into the brain after intravenous injection was their solubility reaction. This, they state, is a peculiar and not a general lipoid one. It corresponds to a solubility in chloroform and in water or perhaps their partition coefficient in these liquids. It is probable that the same may be true of the spinal tissues owing to their similar composition and, from this standpoint, as stated by Rudolf and Bulmer, one would not expect to find arsenic in the tissues of the central nervous system. However, as shown by Voegtlin and his associates, arsenic is to be found in the brain of rabbits after the intravenous injection of arsphenamin, neoarsphenamin, sulpharsphenamin and other organic arsenical compounds, and while the results of similar studies of the tissues of the central nervous system of human beings succumbing to disease or accident during the course of arsphenamin administrations are not available, it is entirely likely that arsenic is deposited in the brain and spinal cord after the intravenous and intramuscular injection of organic arsenic compounds; furthermore, the evidences of toxic neurotropism sometimes exhibited after the administration of organic arsenic compounds, and especially those of the pentavalent type, is confirmatory evidence.

This brings up the question of whether or not the organic arsenical compounds or the arsenic of these are to be found in the cerebrospinal fluid after intravenous injection; probably no subject concerning the distribution and fate of these compounds employed in the treatment of syphilis has excited as much discussion with particular reference to the treatment of the various forms of neurosyphilis. While the exact origin of the cerebrospinal fluid is as yet unknown, it is likely that under physiological conditions this fluid is a form of secretion of the choroid plexus and ependymal cells which effectually prevent the passage of most drugs into the spinal fluid. Hexamethylenamin, uranin and chloroform may pass through and especially the former, but from the standpoint of the drugs employed in the treatment of syphilis, it may be stated that mercury has never been found in the cerebrospinal fluid except when it was injected directly into the subarachnoid space, and Catton[25] and Mehrtens[26] failed to find iodin even after intravenous injections of the iodids. In trypanosomiasis and syphilis of human beings involving the brain, it is possible that drugs may more readily pass from the blood into the spinal fluid; this is especially true in paresis, as indicated by the frequency with which antisheep hemolysin is found in the spinal fluid (Weil-Kaffka reaction), and it is almost certain that in syphilitic meningitis substances in the blood, including drugs, may find their way more readily into the cerebrospinal fluid by extravasation from the congested vessels of the meninges. This is furthermore suggested by the reports of Mehrtens and MacArthur[27] and other investigators, showing that the amount of arsenic in the cerebrospinal fluid after the intravenous injection of arsphenamin and neoarsphenamin may be increased by the injection of sterile serum which induces a mild reaction of the meninges designated as "aseptic meningitis," although it must be likewise stated in this connection that Stillman and Swift[28] and Hall, Callender and Holmbad[29] reported that the intraspinal injection of salt solution or serum did not increase the amount of arsenic in the spinal fluid after the intravenous injection of salvarsan.

It is hardly profitable here to review in detail the rather large literature bearing upon analyses of the cerebrospinal fluid for arsenic after the administration of arsphenamin and neoarsphenamin, since some investigators do not appear to have employed acceptable methods and have not sufficiently controlled the factor of normal or physiological arsenic. Sicard and Bloch[30] recovered arsenic in three out of ten cases after the intravenous injection of salvarsan, but none after intramuscular injections; Wechselmann[31] likewise found arsenic in the spinal fluid of a few cases after intravenous injections of salvarsan. Camp,[32] Ravaut[33] and Hall[34] found traces in the spinal fluids of a few cases, while Engman and his associates[35] and Citron[36] have reported negative results. Barbat[37] found arsenic in the spinal fluid in about 69 per cent. of cases when spinal puncture was conducted immediately after the intravenous injection of 0.4 gm. of salvarsan, while spinal fluids of 26 cases examined twenty-four hours later showed the presence of arsenic in all but one. Mehrtens and MacArthur[38] found arsenic in the spinal fluids of 43 per cent. of cases after the intravenous injection of 0.6 gm. arsphenamin; spinal drainage did not appear to increase the arsenic content, although intravenous injections six hours after the production of meningeal irritation resulted in the penetration of arsenic to the spinal in 92 per cent. of cases. Corbus, O'Connor, Lincoln and Gardner[39] report that the intravenous injection of hypertonic saline solution increased the amount of arsenic in the cerebrospinal fluid after the intravenous injection of arsphenamin. Cornwall and Myers,[40] in a study of spinal fluids from 151 cases of neurosyphilis treated with intravenous injections of 0.1 to 0.2 gm. of silver arsphenamin, claim that arsenic was to be found in quantitative amounts in 78 per cent. of cases two hours later and in 68 per cent. at the end of seventy-two hours.

The observations of Clausen and Jeans have proved especially interesting because they show that the penetration of arsenic into the spinal fluid is modified by syphilis and that more is to be found in cases of neurosyphilis than in normal children. These investigators also observed in several cases that the arsenic in the spinal fluid did not increase after repeated intravenous injections of arsphenamin; on the contrary, the arsenic was progressively increased.

Voegtlin and his associates found that the average arsenic content of the cerebrospinal fluid of eight normal rabbits, which were fed for several weeks on oats and kale in a special room, was 0.69 micromilligrams per gram of fluid, with a maximum of 1.55 and a minimum of 0.5 micromilligrams. These traces of arsenic represented the so-called physiological or "normal" arsenic derived from the traces of arsenic consumed with the food and drinking water. After the intravenous injection of arsphenamin (disodium salt) in dose of 0.040 gm. per kilo the maximum increase of arsenic in the spinal fluid was found about four hours later and amounted to 40 micromilligrams. At this time the blood arsenic was about 15 and the brain arsenic about 2 micromilligrams. The brain tissue of normal control rabbits contained an average of 0.02 micromilligram of "normal" or physiological arsenic and while it is difficult to properly evaluate the results insofar as penetration of arsenic into the brain tissue is concerned, since the arsenic found may be that in the blood, Voegtlin was of the opinion that the brain arsenic was actually increased since there was no parallelism between brain and blood arsenic; at any rate, there can be no doubt of the increase of spinal fluid arsenic which at this time interval was almost three times higher than the blood arsenic.

After the intravenous injection of neoarsphenamin in dose of 0.064 gm. per kilo, the arsenic content of the blood, brain and spinal fluid four hours later was about 3, 0.2 and 30 micromilligrams respectively, showing a very distinct increase of arsenic in the spinal fluid; at the end of 30 minutes the arsenic content of the spinal fluid was about 35 micromilligrams, which was the maximum in comparison with the maximum of 45 micromilligrams of arsenic 210 minutes after the intravenous injection of arsphenamin.

In a study by Fordyce, Rosen and Myers[41] of the arsenic content of the spinal fluid of 27 patients treated with intravenous injections of 0.9 gm. neoarsphenamin followed in from 24 to 30 hours by the injection of auto-serum intraspinally according to the Swift-Ellis method, it was found that 88.5 per cent. of the spinal fluids showed the presence of arsenic at the time of at least one examination, varying in amount from a trace of 83.6 mg. of metallic arsenic per 100 grams of dried specimen.

In a similar study[42] of 63 patients suffering with various types of neurosyphilis, many in an advanced stage of the disease, and treated with intravenous injections of 0.4 gm. arsphenamin followed by the intraspinal injection of auto-serum, a total of 257 spinal fluids were examined at intervals varying from 30 minutes to 4 months; of these 257 fluids, 88 per cent. showed the presence of arsenic at the time of at least one examination, varying from a trace to 73 mg. per 100 gm. of dried specimen.

In an additional study[43] of 72 spinal fluids from 40 patients with syphilis in various stages of the disease treated with intravenous injections of 0.4 gm. arsphenamin followed by withdrawal of 20–40 c.c. of spinal fluid at varying intervals, Fordyce and his associates found no arsenic in 17 per cent. of the fluids, while traces to 54.3 mg. per 100 gm. of dried fluid were found in 83 per cent. of fluids.

These very extensive investigations have shown, therefore, that after a series of intravenous injections of arsphenamin, some arsenic is to be found in the spinal fluids of over 80 per cent. of cases of syphilis at least some one time; the number showing arsenic is slightly increased, however, when patients are treated in addition with an intraspinal injection of auto-serum removed from 50 c.c. of blood drawn after the intravenous injection of arsphenamin or neoarsphenamin.

Voegtlin and his associates found that sulpharsphenamin injected intravenously was more active in the destruction of trypanosomes placed in the subarachnoid space of the cerebral meninges than either arsphenamin or neoarsphenamin; yet the amounts of arsenic to be found in the brain tissue and cerebrospinal fluid after the intravenous injection of sulpharsphenamin was much less. In these experiments sulpharsphenamin, tryparsamid and 3-amino-4-oxyphenyl arsonic acid proved of most therapeutic power, although, as previously stated, the degree of penetrative power did not bear a relation to the amounts of inorganic arsenic recovered from the brain and cerebrospinal fluid six hours after the intravenous injections; it may be quite possible that arsenic penetrates at a later period in larger amounts. Neoarsphenamin proved slightly more efficient than arsphenamin and both of these were more efficient than silver arsphenamin. Curiously, the aromatic pentavalent arsenical compounds, as tryparsamid, arsacetin and atoxyl, appeared to possess greater therapeutic activity in these experiments than these well-known arsphenamins and sulpharsphenamin proved the most effective of the arsenobenzene derivatives studied.

Furthermore it cannot be definitely stated just how far arsphenamin and neoarsphenamin contained in serum or saline solution and injected into the subarachnoid space of the spinal cord, are distributed. The circulation of the spinal fluid appears to be very slow. According to Cavazzani[44] and Hill,[45] substances injected into the subarachnoid space of the cord require from twenty minutes to two hours for general distribution. The direction of circulation appears to be from the ventricles outward and downward; an active circulation toward the ventricles has not been demonstrated, although substances injected intraspinally may become widely diffused in the subarachnoid space. Dandy and Blackfan[46]

have shown, for example, that, after intraspinal injections of finely divided carbon, there was rapid distribution of the particles throughout the subarachnoid space. They showed also that phenolsulphonphthalein injected intraspinally was demonstrable in fluid obtained a few minutes later from the ventricles; these observations naturally possess a bearing upon the distribution of drugs injected intraspinally and indicate that arsphenamin or neoarsphenamin injected intraspinally very probably diffuse upward with wide distribution in the subarachnoid space of both cord and cerebrum.

Elimination of Arsphenamin, Neoarsphenamin, Tryparsamid, and Allied Drugs.—Before discussing the relation of distribution and storage of arsenic in the different tissues following the administration of arsphenamin, neoarsphenamin and allied drugs in relation to the treatment of syphilis, it is first necessary to review briefly our information regarding the elimination of these compounds after intravenous and intramuscular injections.

Elimination of Arsphenamin and Allied Drugs from the Blood.—In the first place, how long does arsphenamin and its allied drugs remain in the blood after the intravenous injection of the usual amounts (0.3–0. 6 gm.) employed in the treatment of syphilis? Tests for salvarsan itself made by the Abelin method have shown very rapid elimination. Thus Treupel[47] found that, after the intravenous injection of 0.4 gm. salvarsan dissolved in water, the average time of disappearance from the blood was thirteen and one-half hours, whereas after the injection of the same amount dissolved in serum it disappeared in twelve hours. Similar results were observed by Spiethoff[48] and the results interpreted as indicating that salvarsan dissolved in serum was less toxic, more rapidly removed from the blood and stored in the organs with consequently more time for elimination.

Robertson and Klauder[49] were unable to find any salvarsan in blood removed ninety minutes after intravenous injections, although positive reactions were observed after ten and fifteen minutes. Schreus and Holländer,[50] applying the same test, were never able to detect salvarsan in the blood serum more than three hours after injection. Fifteen minutes after injection, only about 30 per cent. of the salvarsan was found in the blood and only 20 per cent. at the end of thirty minutes. Neither the dose (0.3 to 0.6 gm.) nor the number of injections had any influence upon the duration of salvarsan in the blood, which argues against a cumulative effect. However, since salvarsan has been detected in the urine by Abelin's method for 24 hours after intravenous injection, it is possible that small amounts may circulate for that length of time at least.

The elimination of arsphenamin and neoarsphenamin from the blood has also been studied by means of quantitative arsenic determinations. Barbat and Myers found that, after the intravenous injection of arsphenamin or neoarsphenamin, only about 25 per cent. could be recovered as arsenic one-half hour later. Clausen and Jeans, employing a modification of Gutzeit's method for quantitative arsenic determinations, found that little or no arsenic was present in the corpuscles after the intravenous injection of arsphenamin but that all was present in the plasma or serum. These investigators also observed that, after the intravenous injection of children with about 0.010 gm. of arsphenamin per kilogram of weight, arsenic rapidly disappears from the circulation, only 50 per cent. remaining for ten minutes and only 10 per cent. at the end of one hour. After the first hour, the rate of disappearance of arsenic was much slower and remained almost constant for six hours.

Webster[51] found ½ to ⅓ mg. of arsenic per 100 c.c. of blood one hour after the intravenous injection of 0.6 gm. arsphenamin; after the administration of 0.9 gm. neoarsphenamin, ⅕ mg. of arsenic per 100 c.c. of blood was found twenty-four hours later, and $\frac{1}{10}$ mg. and $\frac{1}{40}$ mg. after 2 and 5 days respectively. Young[52] in an interesting experimental study, found that, if the serum of goats previously injected with arsphenamin is dialyzed, some of the arsenic is removed, but that the balance is bound to the serum and cannot be dialyzed nor give the usual qualitative reactions. Young found that the inorganic arsenic compounds did not behave in this manner and concluded that it is the arsenic which is bound in the blood and tissues that is slowly eliminated in the urine and feces.

Fordyce, Rosen and Myers[53] have determined the arsenic content of the blood of syphilitic and a few non-syphilitic persons at varying intervals after the intravenous injection of arsphenamin, silver arsphenamin, neoarsphenamin and tryparsamid; *immediately* after injection as much as 37.9 to 66.1 per cent. of arsenic had already disappeared from the blood. During the first twenty-four hours there was observed a gradual lowering of the arsenic equilibrium in the blood after the injection of both arsphenamin and silver

arsphenamin, followed by a marked increase with a gradual diminution at later intervals. Abnormal values, both high and low, for any given interval (partition coefficient) were met with in certain individuals with an arsenic idiosyncrasy or predisposition to intoxication by the drug and rapid disappearance of the arsenic from the blood may be a warning, in the opinion of Fordyce and his associates, of latent arsenical intoxications. In other words, the rate of excretion and retention of arsenic after intravenous injections of arsphenamin is irregular with two well-defined groups which may be classified as "short period" and "long period;" this renders difficult the selection of the most suitable interval for obtaining arsphenaminized serum for intraspinal therapy. Similar results have been reported by Wechselmann and his associates.[54]

I have studied this question of elimination of arsphenamin and neoarsphenamin from the blood by applying a trypanocidal test and the results have proved very interesting and especially useful, since they indicate the duration of the therapeutically active arsphenamin or oxidation products, which after all is of most practical interest in relation to the treatment of syphilis. These tests were conducted by injecting a series of white rats intravenously with 0.005 gm. arsphenamin (disodium salt) and 0.010 gm. neoarsphenamin corresponding respectively to 0.3 and 0.6 gm. per 60 kilo and subsequently infecting animals of both series by intraperitoneal injections of 500,000 Tr. equiperdum 1, 2, 3, 4, 5, 6, 24, 48, 72 and 96 hours later. Rats infected one to six hours after intravenous injections of both drugs usually remained sterile and lived indefinitely, while untreated controls died on the fifth day; animals infected twenty-four to ninety-six hours and longer after intravenous injections of both drugs in the doses mentioned invariably developed trypanosomiasis and died on the fifth to seventh day. These experiments have indicated, therefore, that both arsphenamin and neoarsphenamin and their therapeutically active oxids are rapidly removed from the blood, although, of course, when larger doses were injected, the effects were prolonged for periods slightly greater than just described.

Elimination of Arsphenamin and Neoarsphenamin in the Urine.—A large number of investigations have been devoted to a study of the elimination of arsphenamin and allied compounds as such in the urine and more especially to the elimination of arsenic in the urine and feces after the administration of these drugs. These determinations have had great interest and value in yielding information regarding the fate of these medicaments and the route and rate of their excretion; they have also yielded information bearing upon the mechanism of their therapeutic activity as well as upon the toxic effects sometimes following their administration.

In 1911 Abelin developed a method for the detection of arsphenamin itself in the urine after intramuscular and intravenous injections. This diazo color reaction is merely an indication of the presence of an aromatic amino group, but is regarded by Abelin as specific for the presence of the R-As = As-R radical. In the examination of the urine of thirty-four cases of syphilis, he found that arsphenamin could be demonstrated within five to fifteen minutes after an intravenous injection with negative reactions usually after five or six hours thereafter. In his opinion the rapidity of excretion of arsphenamin and allied drugs is related to the patient's general condition, although he found excretion irregular in that, when the same dose is given several individuals, a marked reaction occurs in some with weak or negative reactions in others.

Leredde and Rubinstein[55] have applied the test to a series of 435 patients receiving 0.15 to 1.2 gm. neoarsphenamin intravenously and in eight of these elimination was delayed, all of the latter being in the chronic stages of syphilis. In their experience elimination usually began in five minutes and was completed in twenty-four hours, the degree and duration of elimination being proportional to the amount injected. They further ascertained that in patients who had received eight, ten and fifteen injections in a course, elimination remained normal.

Escallon,[56] Rieber,[57] Koetter,[58] Authenried and Taege[59] and others have reported more or less favorably upon this test as a means for determining the rate of elimination of arsphenamin, neoarsphenamin and allied drugs. The majority have observed that elimination begins within the first hour after intravenous injections and that it is completed within twenty-four hours. Koetter found that, after the intravenous injection of 0.4 gm. arsphenamin dissolved in water, the drug disappeared from the urine in nineteen hours, whereas when dissolved in the patient's serum it was more slowly eliminated, being found present for forty-two hours. Similar results were reported by Bergmann[60] on the basis of arsenic determinations and the results have been interpreted as showing that arsphenamin and neoarsphenamin dissolved in serum are less toxic, less rapidly eliminated and consequently therapeutically active for longer periods.

Recently, Beeson and Albrecht[61] have reported favorably upon the Abelin reaction applied to urine and believe that it possesses real value as a simple and sensitive test for arsphenamin and neoarsphenamin. In their experience it is specific for these and allied drugs and other substances of the benzene series, as acetylsalicylic acid, acetphenetidin, antipyrin and the salicylates were found not to give the reaction either directly in the test-tube or in the urine after administration. Urine from patients with pneumonia, nephritis, rheumatism and gonorrhea were also tested and found to yield negative reactions. By a slight ring modification of the Abelin test they have been able to detect arsphenamin in the test-tube in amounts as small as 0.0001 to 0.0003 gm. in 10 c.c. of water and neoarsphenamin in amounts as small as 0.0001 to 0.0002 gm. in 10 c.c. of urine. After the examination of the urine of fifty cases of syphilis treated with intravenous injections of neoarsphenamin in concentrated solutions, they concluded that the test was not only specific and very sensitive but of some practical value. In their experience elimination was somewhat slower than reported by Abelin, but usually complete in twenty-four hours; in cases where elimination is greatly retarded or does not occur at all, they believe that a careful examination of the patient is required before treatment is continued.

My experience with this test has not been satisfactory. When arsphenamin or neoarsphenamin were added to water or normal urine, satisfactory reactions were observed even with the small amounts mentioned by Beeson and Albrecht; but tests of the urine collected at intervals of 1, 2, 3, 4 and 24 hours after intravenous injections of 0.6 gm. arsphenamin or 0.9 gm. neoarsphenamin have generally yielded uncertain and unsatisfactory reactions. Sometimes a sufficiently certain and clear reaction was observed with one-hour urine, but after that the usual yellowish-brown color yielded by all specimens, irrespective of the administration of the drugs, interfered with the detection of the color reaction supposed to be produced by the eliminated drugs. I can readily enough understand that a test of this sort for determining the eliminative powers of the kidneys may prove of considerable value and especially with cases presenting toxicological effects, as a means for controlling dosage and indicating extra care in treatment of elimination were found to be below a normal average, but in my experience the Abelin reaction and its modifications have failed to yield reactions and information of this sort in actual practice.

Elimination of Arsenic in Urine, Bile and Feces, after the Administration of Arsphenamin, Neoarsphenamin and Allied Drugs.—The majority of investigators, however, have studied the elimination of arsphenamin and its substitutes by quantitative arsenic determinations, since it is well known that arsenic may be eliminated in the urine and feces for days and weeks after the Abelin test has yielded negative reactions. Sieburg,[62] for example, found that none or only a very small part of the arsphenamin is excreted as such in the urine, pentavalent organic arsenical compounds and inorganic arsenites being usually recovered. The literature up to 1913 has been thoroughly reviewed by Ullman;[63] unfortunately, however, many of the earlier investigations possess but little value or interest because of faulty methods employed for the destruction of the organic matter, for the quantitative determination of arsenic and failure to check adequately the "normal" or physiological arsenic that may be present due to absorption from food, drugs, etc.

Ullman, however, has made a limited number of daily analyses of the urine and feces of patients receiving intravenous injections of arsphenamin, using the hydrochloric acid potassium chlorate method for destroying organic matter and determining arsenic by the Marsh mirror method after converting it into a sulphid. His check analyses indicate that 26 per cent. of the arsenic was lost in the process of destruction of organic matter. In the urine of the first of his series of patients, who received 0.4 gm. arsphenamin intravenously, he detected during the first three days 3.9, 3.1 and 1.4 mg. arsenic, respectively. This is equivalent to a total of 7 per cent. of the amount of arsenic administered. With doses of 0.3 gm. arsphenamin he found in one patient 4.6, 2.2 and 1.6 mg. arsenic, respectively, during the first three days, and in another patient 8.2, 2.7, 0.3, 0.8 and 0.1 mg., respectively, during the first five days. The percentages of elimination during the first three

days were 9.3 and 12.2 per cent., respectively. Since then detailed studies have been published by Frenkel-Herden and Navassart,[64] Wilcox and Webster,[65] Lockemann,[66] Bergman,[67] Weiss and Raiziss,[68] Clausen and Jeans,[69] Bernstein,[70] Fordyce, Rosen and Myers[71] and others but with varying results largely because of the different methods employed. For example, Weiss and Raiziss, employing a modification of the Green iodometric micro-titration method, studied elimination of arsenic in three cases of chronic syphilis with optic atrophy after the intravenous injection of 0.6 gm. of alkalized arsphenamin dissolved in 120 c.c. of distilled water and given twice weekly, weekly or fortnightly. Very small quantities of arsenic, detectable only by very delicate methods of analysis, were found in the daily urine. Thus, after a dose of 0.6 gm. containing from 187 to 188.6 mg. arsenic, from 3 to 8.8 per cent. was eliminated in three days and from 4.9 to 13.5 per cent. in the course of a fortnight. By far the greatest amount of arsenic eliminated by the kidneys was, therefore, found in the urine of the first three days after injection. During the succeeding days, the amounts gradually declined, until by the fourteenth day they usually fell to a level of from 0.1 to 0.5 mg. which approaches the limit of accuracy of the method used. Only a small part of the arsenic derived from arsphenamin was eliminated, therefore, by their three patients through the urine, 13.5 per cent. being the highest amount in fourteen days. The elimination was larger after the second and third doses than after the first. But using constant doses of 0.6 gm. arsphenamin, there was considerable variation in the amounts of arsenic eliminated during a given interval of time by any one patient as well as by the three different patients presumably in the same chronic stage of syphilis and treated under the same conditions

Clausen and Jeans employing a modified Gutzeit method, have made arsenic determinations of the urine during ½, 1, 3, 12 and 24 hour intervals following the intravenous administration of arsphenamin (disodium salt) to children in dose of 0.010 gm. per kilo; also of daily total specimens thereafter for two weeks or more. The rate of excretion was at first very high, as would be expected from the high arsenic content of the blood at this time. After dropping to a minimum at 20 to 60 hours, the rate of excretion in all cases but one rose to a maximum at 55 to 132 hours, after which the level steadily fell.

Bernstein concluded from his study that, while the arsenic elimination after the injection of sulfoxylate salvarsan is high during the first six hours, yet as a whole the compound is more slowly oxidized than silver salvarsan and neosalvarsan and thereby longer retained with more prolonged therapeutic effects. Lockemann[72] had previously shown that neosalvarsan was more rapidly eliminated than arsphenmin, but recently Galonnier[73] reported that after intravenous and intramuscular injections of sulfarsenol and neoarsphenamin the elimination curves were quite similar. After the intravenous injection of sulfarsenol, arsenic was found in the urine in one hour; after the injection of neoarsphenamin, arsenic was found in ten minutes; but both reached the maximum of excretion at the end of the first day. After intramuscular injections, the maximum excretion of arsenic was at the end of the second day for both compounds.

It was soon discovered by the Navassarts[74] and others that large amounts of arsenic were to be found in the *feces* after the administration of arsphenamin and neoarsphenamin and at first this was ascribed to elimination through the intestinal wall until Obregia and Carniol[75] showed that arsenic was actively eliminated through the bile, being found as early as twenty-five minutes after the intravenous injection of neoarsphenamin. Pomaret[76] also found 10 mg. of arsenic in 5 c.c. of dog's bile collected one hour after the intravenous injection of 0.3 gm. neoarsphenamin.

Subsequent investigations have shown that from three to five times more arsenic is to be found in the feces than in the urine; Clausen and Jeans, for example, have found five times more in the feces than in the urine of children injected intravenously with 0.010 gm. arsphenamin (disodium salt) per kilo of weight. Recently Underhill and Davis[77] have likewise found that, after the intravenous injection of arsphenamin and neoarsphenamin, the total percentage of arsenic excreted in the feces is larger than in the urine, being as high as 53.76 per cent. in one week. They observed that arsenic appeared in the urine within a few hours after intravenous injections, but more slowly in the feces (three or four days), the maximum excretion occurring in the urine on the same or following day. In a series of injections, the arsenic excretion was found small in the first interval in both urine and feces, but increased after each succeeding injection. This is due to the larger amount of arsenic stored in the liver after the administration of all arsenic compounds including the organic trivalent and pentavalent compounds, with elimination through the bile.

In addition to elimination through the bile, some arsenic is apparently excreted by the *intestinal mucosa*. Analyses have shown the presence of arsenic in these tissues and it is well known that arsenic may produce histological changes in the epithelium composed largely of cloudy swelling and fatty degeneration along with hyperemia of the submucosa. Of course, these changes may be due to the absorption of arsenic from the bile, but at present pharmacologists are in general of the opinion that these effects are due to elimination.

Up to the present time, however, elimination through the *bile* has been studied exclusively on animals, although the readiness with which bile can now be obtained from human

subjects by the Meltzer-Lyon method opens up a means for the study of elimination by this route and it is possible that future investigations will develop a practical means for determining the elimination of arsenic from the kidneys and liver after the first dose or two of arsphenamin, neoarsphenamin or allied compounds employed in the treatment of chronic syphilis as a means for preventing such accidents as icterus and dermatitis which may be caused by faulty elimination.

As will be shortly discussed with more detail, the investigations of Voegtlin and his associates have shown that the excretion of arsenic varies considerably in different normal rats after the administration of any one compound and that elimination after the injection of the different organic arsenicals varies greatly according to their chemical constitution as affecting their physical properties. Arsphenamin, for example, is largely eliminated by the liver in the bile; neoarsphenamin and atoxyl, by the kidneys in the urine; etc. Ligation of the common bile duct in aminals increased, therefore, the toxicity of arsphenamin but not of atoxyl and only slightly of neoarsphenamin.

Elimination of Arsenic in Perspiration, Skin, Vomitus, Saliva and Milk.— In 1912, Ullman[78] found a questionable trace of arsenic in the *perspiration* of a patient after the intravenous injection of arsphenamin, and recently Fordyce and his associates[79] have greatly renewed interest in the presence of arsenic in the skin. As stated by these authors, arsenic is known to have a marked affinity for epithelial cells and in chronic poisoning may produce a wide variety of cutaneous lesions. It is possible that dermatitis exfoliativa may have this origin and especially if there is present a coexisting peripheral neuritis; in their opinion, when normal elimination of arsenic through the skin is interfered with, its deposition in the cutaneous layers is sufficient to produce irritation and consequent edema which interferes with the functional activity of the skin and results in the production of dermatitis. Analysis of scales from 22 cases of syphilis, developing desquamating rashes after the administration of arsenical compounds, showed the presence of arsenic in 20, the amounts varying from 0.123 to 315.9 mg. Six batches were from non-syphilitic cases and showed from a trace to 1.63 mg. of arsenic; three of these cases were known to have received arsenious acid or cacodylate of soda.

Obregia and Carniol, previously mentioned, have demonstrated the elimination of arsenic in *saliva* after the administration of neoarsphenamin and this observation is of interest in connection with the well known clinical observation that the majority of patients complain of ether taste during the administration of neoarsphenamin and allied drugs.

It is also of interest that Weiss and Raiziss observed arsenic in the *vomitus* of one case four hours after the intravenous injection of arsphenamin; this may have been due to regurgitation of bile from the duodenum or elimination by the gastric mucosa.

It is well known that a syphilitic child, nursing its mother while the latter is under treatment with arsphenamin or neoarsphenamin, shows clinical effects; indeed, this method of treating the syphilitic infant is of considerable practical value, as I shall discuss in a later chapter. Undoubtedly the drugs must be excreted in the *milk* in a therapeutically active state in at least small amounts and analyses of the milk of lactating women under treatment with arsphenamin and neoarsphenamin have usually shown the presence of arsenic.[80] The literature is reviewed by Fordyce, Rosen and Myers[81] who likewise analyzed the milk of fifteen women for "normal" arsenic with generally negative results. They also examined the milk of twelve women after the intravenous injection of 0.2 to 0.3 gm. arsphenamin and concluded that a nursling probably receives sufficient arsenic in its daily feedings to be of some therapeutic value. Therefore, the energetic treatment of syphilitic mothers during lactation is advisable in order that the infant may have the benefit of this simple method of administration in addition to the other forms of treatment.

Variations in the Rate of Elimination of Arsenic.—As shown by Voegtlin and Thompson,[82] the rate of excretion of arsenic by different rats, following the intravenous injection of various organic arsenical compounds, has varied considerably and in their opinion this variation in the rate of excretion in different individuals is one of the important factors regulating toxicity and therapeutic activity. According to their results, variations in the rate of excretion of arsenic may occur not only in cases of impaired kidney function but also in cases of normal renal function, which may account for some of the toxic reactions sometimes observed in human subjects presenting no manifestations of renal disease. In this connection it may be stated that they observed greater variations in the rate of excretion of the arsenic of neoarsphenamin than in the case of arsphenamin, and, as I shall discuss in Chapter XLVI, it is significant that the arsenic of the former is more irritating to the kidneys of rats than the arsenic of the latter.

The directly toxic trivalent oxid compounds, as "arsenoxid," showed the slowest rate of excretion, and these are the drugs most toxic for both host and parasites, although in their experiments there was no direct relation between rate of elimination, toxicity and trypanocidal activity due, probably, to differences in the physical properties of the compounds with special reference to their solubility in the body fluids.

The pentavalent arsenical compounds with the exception of arsenic acid, were eliminated most rapidly, while the arsenobenzene compounds occupied an intermediate position. The ratio between urinary and fecal excretion of the arsenic of these different compounds also showed great variations in otherwise normal rats. There is no reason to doubt but that similar conditions exist among human beings and probably even to a greater degree, since elimination by both the kidneys and bile may be still further reduced or altered as a result of syphilis or previous medication.

Variations in the Physical and Chemical Constitution of Arsenical Compounds in Relation to Elimination of Arsenic.—According to Voegtlin and Thompson the rate of excretion of arsenic appears to bear a relation to the chemical constitution of the arsenical insofar as this determines physical properties. The rate of excretion, toxicity and therapeutic activity were found not to bear a direct relation to each other in the case of the trivalent oxids, which lack of correlation they have ascribed as probably due to differences in physical properties, particularly the solubility of these compounds. In addition, molecular weight, surface tension, electric charge and dissociation are mentioned as probable important factors having a bearing on the route and rate of excretion, although information relating to the physical properties of the compounds studied by them was very meager. The arsenic of arsphenamin was found to be largely excreted by the liver, whereas that of the corresponding oxid was excreted mainly by the kidneys which is probably due to a difference in the distribution of these compounds in the body as previously discussed, since the same physical factors as modified by chemical constitution are believed to modify the distribution of the organic arsenical compounds.

Retention and Elimination of Arsphenamin, Neoarsphenamin and Allied Drugs in Relation to the Treatment of Syphilis.—And now it is profitable to inquire what relation the results of these investigations upon the retention and elimination of arsphenamin, neoarsphenamin and allied drugs bear to the treatment of syphilis, especially the retention and elimination of the pentavalent organic arsenic and inorganic arsenic derivatives of these compounds. Insofar as retention is concerned, it may be stated that our main interest is in the question whether or not the retained arsenic is therapeutically active; the

question of elimination is of chief interest in relation to the toxicological effects produced by deficient excretion and stored arsenic.

In the first place, it is apparent that arsphenamin, neoarsphenamin and their therapeutically active "oxids" are rather quickly eliminated from the blood and that, indeed, these drugs may be eliminated in part at least in the urine and bile unchanged. From this we may conclude that only a portion of these drugs injected intravenously exert curative effects in the blood, lymph and tissues, owing to the rapidity of elimination; after intramuscular and subcutaneous injections, elimination is of course much slower and for this reason it is highly desirable to have at our command a therapeutically active arsenical compound that may be repeatedly administered by these routes in adequate amounts. It does not appear that the *amount* of these drugs administered at one time has any important relation to rapidity of elimination, that is to say, after the injection of small doses, as 0.1 gm. to an adult, a portion is rapidly eliminated as well as after the injection of 0.6 gm., although, of course, more is eliminated in the urine, bile and by other channels after the latter dose than after the former. But there does not appear to be a constant threshold; that is, it does not appear that after a certain small dose all of the drug is retained and utilized and that elimination of the therapeutically active drug occurs only when this amount is exceeded. This point is not without practical significance, because, if it were the case that all of certain small doses of arsphenamin and neoarsphenamin were utilized, it would readily become a principle of treatment not to give more than this dose but to repeat the administrations at such intervals as would maintain this threshold over a sufficient period of time for therapeutic results. As it stands, however, the evidence of investigations summarized above shows that elimination of the active drugs begins promptly after small as well as after large doses and a study of the rate and amount of elimination has not greatly aided us in arriving at conclusions regarding the amount of drug to administer at one time or the frequency of administrations. More helpful data has been obtained by trypanocidal and spirocheticidal tests in infections of the lower animals, as discussed in Chapters XVIII and XXIX. Approximately 50 per cent. of the arsenic of the trivalent and pentavalent organic arsenical compounds employed in the treatment of syphilis is retained by the tissues and slowly eliminated.

Therapeutic Activity of Stored Arsenic.—The question arises regarding the therapeutic activity of this stored arsenic. Of course, it is reasonable to believe that any of these compounds stored in the form of trivalent compounds may be converted into the therapeutically active "oxids" and exert spirocheticidal effects, but it is not known just how long these compounds exist before they are changed into less active substances and I believe that a portion at least of the stored arsenic is in the form of the therapeutically inert pentavalent compounds. Several European authors have laid stress upon the formation of "depots" of drug for slow absorption and prolonged therapeutic effects; I believe in this idea insofar as it refers to the storage of therapeutically active forms of drug as in intramuscular injections, but, as stated above, it is very doubtful if all of the arsenic which we find stored in the liver, spleen and other organs is therapeutically active. Without much doubt, some of this arsenic is re-absorbed into the blood, as indicated by the results of analyses over prolonged periods of time, but does it do any good before final elimination in the excreta? Wechselmann, Lockemann and Ulrich[82] have recently expressed the opinion that clinical observations do not indicate that this arsenic is therapeutically active and that the maximum of spirocheticidal

effects is accomplished during the comparatively short time in which large amounts of active forms of the drug circulate in the blood.

My own experiments have likewise indicated that the arsenic which is stored in the liver of rabbits after repeated intravenous injections of arsphenamin and neoarsphenamin is not therapeutically active. I have injected rabbits intravenously once a week with 0.030 gm. of arsphenamin (disodium salt) for six weeks and then tested emulsions of the liver in saline solution for trypanocidal effects by injecting large amounts into the peritoneal cavities of rats infected with *Tr. equiperdum,* with negative results. In one of these experiments, 100 grams of liver from several treated rabbits was thoroughly macerated and autolyzed under sterile conditions in 200 c.c. of sterile water. After centrifuging briefly to remove the heavier particles, the supernatant fluid was found to contain 0.00035 gm. of arsenic per cubic centimeter. From 1 to 10 c.c. of this fluid, carrying from 0.00035 to 0.0035 gm. of arsenic, was injected into a series of infected rats per kilo of weight with absolutely no influence upon the development and course of the resulting acute trypanosomiasis; untreated controls died on the sixth day after inoculation and controls treated at the same time with intraperitoneal injections of 0.003 gm. of arsphenamin (disodium salt) per kilo lived indefinitely.

Of course, experiments of this kind are not conclusive, but there is nothing to indicate that all of stored arsenic re-absorbed into the blood is again rendered therapeutically active, although it is common clinical experience to observe that after a course of intravenous injections of arsphenamin or neoarsphenamin followed by periods of rest of several months duration, the Wassermann reaction becomes weaker or negative along with clinical improvement. Such occurrences naturally suggest that the stored arsenic has continued to function therapeutically as is probably true of that oxidized into the "arsenoxid" compounds, but that which is further oxidized into pentavalent arsenic is not, unless it aids in stimulating antibody production; the effects upon the Wassermann reaction at least may be due to a continued elimination of the "reagin" from the blood rather than to a further destruction of spirochetes.

Naturally, anything interfering with the rate of elimination of the therapeutically active forms of the organic arsenical compounds may be expected to increase parasiticidal effects. Indeed, as previously mentioned, Voegtlin and Thompson have shown in trypanocidal tests with rats that there is an important relation between rate of excretion on the one hand, and toxicity and parasiticidal activity on the other. This relationship appeared to depend upon the differences in physical properties of the trivalent and pentavalent arsenicals studied. As pointed out by them, changes in the chemical constitution of these compounds affect the physical properties, which in turn determine the rate of diffusion and distribution in the body as well as the route and rate of excretion of the arsenic, thus governing the toxicity for the host and parasites alike. In confirmation of these observations, Voegtlin, Dyer and Miller[83] found that ligation of both ureters increased the toxicity and trypanocidal activity of those arsenical compounds which normally show a rapid rate of urinary excretion, as neoarsphenamin and sodium arsenate. The toxicity and trypanocidal activity were not increased by this procedure, however, for these compounds as "arsenoxid," sodium arsenate and arsphenamin have a low rate of urinary excretion. Complete obstruction of the bile duct increased the parasiticidal action of arsphenamin and neoarsphenamin, but not of atoxyl, and produced only slight changes in the toxicity of neoarsphenamin. The negative results observed with atoxyl were expected, in view of the fact that this compound is eliminated very rapidly by the kidneys;

it was surprising, however, that ligation of bile duct did not increase the toxicity of arsphenamin and neoarsphenamin to a greater extent, which probably was due to a compensatory function of the liver.

While a portion of the stored arsenic may not be therapeutically active or capable of being rendered so after re-absorption into the blood and distribution, there can be no doubt but that it may exert injurious effects. The "arsenoxid" itself may injure the tissues of the host, because toxicity tests on rats have shown that it is at least five to eight times more toxic than arsphenamin but the tissues apparently are able to continue oxidation of this compound to the less toxic pentavalent arsenic which the parasites are not able to do, at least not to the same extent. In this way Voegtlin has explained the toxicity of "arsenoxid" for parasites (parasitropism), without apparent injury of the host (organotropism). But aside from this, I believe that the therapeutically inactive pentavalent arsenic may be injurious to the tissues and anything which hinders its elimination does not benefit the syphilitic therapeutically but may cause injury by toxic effects.

Effects of Arsphenamin and Neoarsphenamin upon Blood Pressure.—In 1915 Rolleston[84] studied the effects of intravenous injections of 0.6 to 0.9 gm. neoarsphenamin upon the blood pressures of one hundred consecutive cases of syphilis, almost all in the secondary stage, and with an average age of 24 years. The pressure (systolic and diastolic) was taken (1) on one or more days before the injection was given, (2) about seven hours after the injection, and (3) on three or sometimes four subsequent mornings. In 19 of these cases the blood-pressure was also taken during the intravenous injection of neoarsphenamin. Included in the 100 cases were 12 cases in which the blood-pressure was investigated in connection with both first and second injections of neoarsphenamin usually at a month's interval. Mercer's sphygmomanometer, with an arm-cuff of 14 cm. was used. The auscultatory method was employed, the maximum systolic pressure being estimated as the mean between the points where the auscultatory sound disappeared and reappeared, and the diastolic pressure at the time of the so-called fourth phase, where the intensity of the auscultatory sound suddenly diminishes. Rolleston took all the blood-pressure estimations himself so that errors from more than one personal equation were avoided. As a result of this thorough study, the following conclusions were reached:

1. The average of both the systolic and diastolic blood-pressures on the days after injection was generally lower than before injection, the fall in the systolic being slightly more marked than in the diastolic pressure. This fall, however, was very probably not a direct result of the action of neoarsphenamin, and, in part at least, may have been due to rest in bed.

2. The blood-pressure seven hours after the intravenous injection of neoarsphenamin was usually lower than it was before. The fall in the diastolic pressure was slightly less than that of the systolic pressure. The fall could not be explained as due to fever.

3. As compared with the blood-pressure taken seven hours after the intravenous injection of neoarsphenamin, the average of the blood-pressure estimations on subsequent days was usually lower. This was more marked in the diastolic than in the systolic blood-pressure.

4. During the actual intravenous injection of neoarsphenamin both the systolic and diastolic pressures were nearly always higher than on other occasions. This appeared to be due to excitement. During the operation the pressures varied considerably, the systolic blood-pressure being more affected than the diastolic.

5. The blood-pressure before the first injection of neoarsphenamin was nearly always higher than the blood-pressure before the second injection of neoarsphenamin, but here again mental excitement may have been responsible.

6. Finally, the general effect of intravenous injections of neoarsphenamin was rather to lower, certainly not to increase, the arterial blood-pressure.

In 1918, Jackson and Smith,[85] in a study of the mechanism of the immediate toxic reactions sometimes following the intravenous administration of

arsphenamin, found that the slow injection of dilute alkaline solutions of arsphenamin (monosodium salt) into anesthetized dogs in doses similar to those administered human beings in the treatment of syphilis, produced no striking results. However, as the rate of injection and the concentration of the drug were increased, symptoms of dilatation of the heart were apparent, perhaps mainly of the right side at first, along with a progressive increase of pulmonary blood-pressure, and a slow, gradual, but not severe, fall of the systemic pressure. Smith[86] subsequently found similar effects produced by the intravenous injection of "arsenoxid." Jackson and Smith, and subsequently Jackson and Raap,[87] found that this increase in pulmonary blood-pressure was not due to contraction of the musculature of the bronchioles, but probably to the effects of obstruction of the pulmonary circulation, due partly to the alkalinity of the solutions, possibly to the presence of embolic precipitates in the vessels, and partly to the specific action of the drug itself on the musculature of the arterioles.

Similar studies do not appear to have been made with neoarsphenamin, but, since solutions of this drug are approximately neutral, do not produce "nitritoid crises" as frequently as arsphenamin and are very much less likely to produce intravascular agglutination of erythrocytes and serum precipitates, I believe that it is highly probable that similar effects upon the pulmonary blood pressure are not produced.

In brief, therefore, it may be stated that the slow intravenous injection of 0.6 gm. arsphenamin in alkaline solution, well diluted in at least 100 to 150 c.c. of water, does not produce any noticeable effects upon the general systemic or pulmonary blood-pressures; certainly there is no increase of general systemic blood-pressures produced by neoarsphenamin, as shown by Rolleston. When arsphenamin is injected in acid solutions, which produce marked agglutination of erythrocytes and heavy precipitates in the blood, embolism occurs in the lungs with a greatly increased blood pressure; apparently no effect, however, is exerted upon the musculature of the bronchioles which speaks against an anaphylactic basis of the acute clinical reaction partly caused by this pulmonary embolism. It may be that the alkali and the drug itself also cause some muscular constriction of the pulmonary vessels and thereby increase pulmonary pressure with or without the embolism. This results in increased work for the heart which may dilate or pass into delirium cordis, but, since these are toxicological effects, I shall discuss the subject with more detail in a succeeding chapter concerning the "nitritoid crisis" and other arsphenamin reactions. Suffice to state that in ordinary doses properly administered to human beings, the pharmacological effects of arsphenamin and neoarsphenamin upon the general and pulmonary blood-pressures are slight or altogether without discernible alteration except for the effects that may be produced by excitement or fear, which, of course, are to be differentiated from the effects produced by the intravenous injection of solutions of either drug.

In this connection mention may also be made of the experiments of Joseph,[88] who found that arsphenamin is practically without irritation when applied directly to nerve and muscle tissue of the frog. Also of the study by Perutz and Rosenmann,[89] who found that ordinary doses of neoarsphenamin had no toxic effect on the action of the extirpated gut of warm blooded animals, although some effect was produced upon the gut of cold-blooded animals.

Influence of Arsphenamin and Neoarsphenamin upon Blood Chemistry and Kidney Elimination.—Investigations bearing upon the changes that may be produced by arsphenamin and neoarsphenamin on the normal

chemical constituents of the blood have been particularly interesting in relation to the toxicological effects that may be produced by these drugs in the treatment of syphilis.

Marischler and Schneider[90] investigated three cases of syphilis; one primary, one secondary and one tertiary after the intramuscular injection of acid solutions of arsphenamin. An increased excretion of calcium oxid and phosphorus in the urine and feces was found in all three cases, and in one case there was an increase in the phosphorus to nitrogen ratio, with a corresponding decrease in the nitrogen output. The authors concluded that arsphenamin acts like an acid, combining with the alkali of the body, especially with the calcium of the bone cells.

Rappleye,[91] studied the effects of intravenous injections of arsphenamin in alkaline solution on blood urea and the phenolsulphonephthalein elimination in paretic patients, concluding that arsphenamin has no injurious effects upon the kidneys when their function is good at the outset. Elliott and Todd[92] made similar observations as likewise Anderson,[93] Weiss and Corson;[94] the latter made particularly careful determinations of non protein nitrogen, sugar, uric acid, carbon dioxid combining power of the plasma and elimination of phenolsulphonephthalein. Finally Raiziss and Brown have determined the effects of single large and multiple small doses of arsphenamin (disodium salt) and neoarsphenamin upon the total non protein nitrogen, urea nitrogen and creatinin of the blood of rabbits before and at varying intervals after the intravenous injection of the drugs, with the general result that while the single massive doses of both compounds produced marked nephritis with an increase of non protein nitrogen, urea and creatinin, twelve small doses in amounts corresponding to the amounts ordinarily administered human subjects in the treatment of syphilis, had no appreciable effects. McFarland[96] in a study of the cholesterol of the blood in syphilitic patients found that, in general, the amounts tend to be medium and low rather than high, the results being similar to those expected in a similar series of non-syphilitic individuals, except in some cases of neurosyphilis when the cholesterol content appeared to be increased. The administration of arsphenamin, however, had no effect upon cholesterol content of the blood. Bailey and MacKay[97] however, found hypercholestermia an early and marked sign of toxic jaundice sometimes associated with an increase of uric acid of the blood; studies were also included of bile pigments and salts in the urine and plasma.

It may be stated, therefore, that the administration of arsphenamin and neoarsphenamin in ordinary therapeutic doses at the usual intervals of injection, have no appreciable effects upon the blood constituents or kidney elimination, if the kidneys are functioning normally when treatment is begun. It is, of course, well known that arsphenamin and neoarsphenamin may produce nephritis with changes in elimination but under ordinary circumstances these accidents do not occur and the drugs produce none or but minor and unimportant changes in the blood chemistry and in kidney elimination in the majority of cases of syphilis undergoing treatment with intravenous injections of arsphenamin and neoarsphenamin. In other words these drugs are not ordinarily injurious to the kidneys although other organic and some inorganic arsenical compounds are more renotropic than these drugs.

In this connection I may also state that while Rowe[98] and Tokuda[99] have observed interesting changes in the refractometric indices of the serum in syphilis, the latter has observed that neither arsphenamin nor neoarsphenamin produced any marked or constant influence. Of further interest in this connection was a similar refractometric study by Zimmer[100] to determine

the nature of the increase in weight of syphilitic patients under arsphenamin treatment. Zimmer found that the increase may be true and due to an increase of substance rather than a pseudo-increase from water retention, although sudden increases on weight may be due to retention of water in the blood and tissues as shown by changes in the protein content of the serum. In general, however, the author concludes that arsenic may change the balance between blood and tissues with an increased capacity for mobilization of the tissue fluids in acute osmotic disturbances.

Influence of Arsphenamin and Neoarsphenamin upon the Corpuscular Elements of the Blood.—Arsphenamin and neoarsphenamin are probably erythrogenic to a slight degree, that is, capable of stimulating the bone marrow with an increased production of erythrocytes. In cases of syphilitic anemia, I have frequently observed a steady rise in the number of erythrocytes to normal proportions along with an increase of hemoglobin during treatment with intravenous injections of neoarsphenamin at weekly or biweekly intervals. Likewise in the primary anemias of non-syphilitic origin, the administration of neoarsphenamin is sometimes followed by slight but definite increase of erythrocytes, although the evidences of bone-marrow activity are not as definite as has been observed with germanium. Doubtless the improvement in the anemia of syphilis is due in part to the destruction of the parasites and the removal thereby of their hemotoxins. In chronic syphilis with normal blood pictures, the administration of arsphenamin, neoarsphenamin and substitute drugs are without appreciable influence upon the erythrocytes and hemoglobin; in other words, the effects of arsphenamin and neoarsphenamin in ordinary and usual doses upon erythrocytes and hemoglobin of syphilitic individuals are apparent only when an anemia exists.

Ordinarily an intravenous injection of arsphenamin or neoarsphenamin has no constant influence upon the total or differential leukocyte counts when reactions do not occur. An individual with about 7000 cells per cubic millimeter may show an increase to approximately 9000 when counted within an hour or two after an injection, but at the end of twenty-four hours the count is usually at the pre-injection level. Intramuscular injections of sulpharsphenamin have usually produced a mild leukocytosis (9000 to 12000 cells per c. mm.) at the end of twenty-four hours, along with a slight increase of the polymorphonuclear neutrophilic leukocytes, but these effects are probably due to local irritation of the drug. However, when reactions follow the administration of arsphenamin or its substitutes, and especially in dermatitis, more marked changes in the blood may occur and especially a decrease of the polymorphonuclear neutrophils along with an increase of the large mononuclears and eosinophils. I have observed these changes in the dermatitis so frequently developing after the intravenous or intramuscular injections of sulpharsphenamin and will refer to them again with more detail in Chapter LI, devoted to a discussion of the toxicological effects of arsphenamin and its substitutes, as likewise the aplastic anemias characterized by leukopenia, eosinophilia, lymphocytosis, etc., due to toxic destruction of the bone marrow sometimes produced by arsphenamin.

Effects of Arsphenamin and Neoarsphenamin upon the Coagulability of the Blood.—Ordinary therapeutic doses of arsphenamin do not appear to alter the coagulation time of the blood of human subjects but large doses may produce profound changes in experimental animals. Flandin and Tzanck[101] for example, have called attention to the incoagulability of the blood of animals receiving large doses of arsphenamin, and from certain experiments came to the conclusion that the lack of coagulation was due to the action of the arsphenamin on thrombin or its precursor.

In a thorough study of this subject Oliver and Douglas[102] came to the conclusion that arsphenamin may produce incoagulability of the blood both in the test tube and rabbit by acting chiefly on the fibrinogen (globulins), rendering the blood incoagulable to heat or thrombin. No action on thrombin could be demonstrated as claimed by Flandin and Tzanck. While the effects observed on the properties of the globulins was similar in nature to that caused by alkali, yet the action of the alkali alone will not explain the results obtained according to Oliver and Douglas, with solutions of disodium arsphenamin. Oliver and his colleagues also found that arsphenamin administered in gelatin solutions did not have these effects, due to the protection afforded by the colloid.

In repeating some of Olivers' experiments I have observed similar effects. The intravenous injection of rabbits with large doses of disodium arsphenamin in saline (0.100 gm. per kilo) invariably rendered the blood incoagulable, whereas similar doses administered in 0.5 to 2 per cent. solutions of gelatin had no such effects.

Neoarsphenamin may likewise reduce the coagulation time of the blood although this subject has not been thoroughly studied. Some years ago Dr. Lake of the Hygienic Laboratory drew my attention to the fact that rats injected with large amounts (0.200 gm. or more per kilo) in the conduct of toxicity tests, not infrequently continued to bleed for an hour or more after injection. This observation has been amply confirmed and the changes in coagulation time are so marked that it is sometimes necessary to ligate the vein after the injection of these animals. With human subjects receiving 0.9 gm. intravenously I have sometimes observed that the coagulation time measured with the Bogg's coagulometer was delayed one to several minutes beyond the pre-injection time, although usually within four hours the delay in coagulation had disappeared.

Effect of Arsphenamin and Neoarsphenamin upon the Epinephrin Content of the Adrenal Glands.—As discussed with more detail in Chapter LI, it is commonly believed that the administration of arsphenamin and neoarsphenamin may bring about changes in the epinephrin content of the blood, since the administration of this substance may sometimes relieve the acute symptoms of the immediate arsphenamin reaction or "nitritoid crisis."

As shown by Brown and Pearce[103] and confirmed by Lucke and myself,[104] the administration of very large amounts of arsphenamin and neoarsphenamin to rabbits and rats may produce histological changes in the adrenal glands, and Hirano,[105] after a study of the epinephrin content of rabbits' adrenals by the colorimetric method of Comessatii, after the intravenous injection of arsphenamin and neoarsphenamin, concluded that large doses of these arsenicals produced a remarkable decrease of chromaffin substance and of residual epinephrin, and that in therapeutic doses arsphenamin caused partial exhaustion, while neoarsphenamin did not influence the epinephrin contents.

In a study of this subject, employing rabbits, by Lucke, McCouch and myself,[106] it was found that doses corresponding to those employed in the treatment of syphilis had no appreciable effects. The adrenal glands were extracted according to the method of Folin, Dennis and Cannon[107] and asayed by the biological method of Elliott.[108] Rabbits injected with doses of 0.02 to 0.1 gm. per kilogram corresponding to 1.2 to 6.0 gm. per 60 kilograms, showed a considerable range of values, but on the average the amounts were almost identical with the average of the epinephrin values of control rabbits.

CHAPTER XLIV

GENERAL CONSIDERATIONS WITH ETIOLOGICAL AND CLINICAL CLASSIFICATIONS OF THE TOXIC REACTIONS PRODUCED BY ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

Even before organic compounds of arsenic were employed for medicinal purposes, the toxicological effects of the inorganic salts commanded a great deal of attention for hundreds of years and especially in relation to chronic poisoning. During the last twenty years, it has been shown that accidental arsenical poisoning is not infrequently due to the widespread presence of the element in beverages, foods, cosmetics and other substances in common use, but, since the introduction of organic arsenical compounds for the treatment of trypanosomiasis, syphilis, and other diseases, interest in the toxicological or untoward effects has been greatly increased and especially since the discovery of arsphenamin and neoarsphenamin. I do not know of any other group of compounds which have been subjected to as much laboratory and clinical study in relation to toxicological effects as these two arsenical substances and since 1910, an enormous literature has accumulated upon the subject.

Importance of the Subject of Toxic Reactions in Relation to the Science of Chemotherapy.—Clinical and laboratory experience with atoxyl and arsenophenylglycin had lead Ehrlich and his associates to expect that untoward effects may be observed in at least some cases of syphilis treated with arsphenamin and especially evidences of neurotropism, but in the early days of salvarsan therapy no one surmised that the subject would assume the importance that subsequent events have developed. Indeed, laboratory and clinical investigations upon the toxicity of arsphenamin and its substitutes have very materially modified early conceptions of the mechanism of toxicity

of drugs in general and have shown that it is not merely a matter of what may happen when a drug has been brought into contact with the fixed cells of various organs, but that other and important reactions may occur in the blood and body fluids before this union occurs and especially if the medicinal compound is administered by intravenous injection.

Few chapters in the history of chemotherapy are as interesting and important as that concerning the toxicology of arsphenamin, neoarsphenamin and their substitutes, not only from the practical standpoint in relation to the treatment of syphilis and other diseases, but also in relation to the science of chemotherapy in general, of which mention may be made of the influence of reactions between the blood and solutions of the drug, the histopathological changes in important organs that may be produced by the drug, the influence of errors in administration, the modifying influence of congenital or acquired hypersensitiveness to the drug, the influence of pathological changes in important organs that may be produced by syphilis and other infections, etc., as examples of the numerous factors to be studied and taken into consideration in relation to the possible toxicological effects of a chemical substance employed in the treatment of disease. In other words, our present knowledge of the manifestations and mechanism of the toxicological effects that may be produced by the organic arsenical medicinal compounds serves as an example of the difficulties to be confronted in chemotherapeutic research and indicate especially that the minimal lethal and maximum tolerated doses of a compound for the *healthy* lower animals are only a part—a small, although a valuable and essential part—of the data required for evaluating a remedy from the standpoint of its possible untoward and harmful effects for the *sick* human being.

Organic Arsenical Compounds of Special Interest from the Standpoint of Toxic Reactions.—Of the very large number of trivalent and pentavalent organic arsenical compounds which have been described since arseno compounds were first prepared by Michaelis in 1881 and recently compilated by Raiziss and Gavron,[1] only those which have proven sufficiently low in toxicity and high in parasiticidal activity to gain a place in the treatment of diseases of human beings or the lower animals require consideration in this treatise. First among these in practical importance are the trivalent compounds arsphenamin, neoarsphenamin, sodium arsphenamin and sulpharsphenamin; among the coördination compounds, only silver arsphenamin has proven worthy of inclusion; among the pentavalent compounds, only atoxyl and tryparsamid require discussion as the others possess no material superiority over these in medicinal value.

In a general manner, the toxic manifestations of these different compounds have certain features in common since the arsenic of all exerts a similar pharmacodynamic effect. Of course, the chemistry of the different compounds exerts important special effects, not only as influencing the effects of arsenic, but also the kinds and amounts of impuritites which may be present by reason of technical factors in their preparation or administration, because of varying primary physicochemical effects upon the blood when administered intravenously, varying selective affinities for certain tissues, etc. For example, solutions of arsphenamin are acid and when injected into the blood in this state without neutralization may produce profound and dangerous physical changes and toxic reactions; some of the pentavalent arsenicals like atoxyl have special affinity for nerve tissue (neurotropism), etc.

Etiological Classification of the Toxicological Reactions Following the Administration of Arsphenamin, Neoarsphenamin and Other Organic Arsenical Compounds.—In a broad and general manner, it may be stated

that the causes, lesions and symptoms of the toxicological effects of arsphenamin and other organic arsenical compounds are numerous and exceedingly complex; I know of no other class of compounds quite as complicated from these standpoints and concerning which so many and diverse factors require consideration.

In the first place, arsphenamin, neoarsphenamin and most organic arsenicals are exceedingly complex chemical compounds, are not crystallizable and therefore difficult or impossible of preparation on a large scale in an absolutely pure state with uniform biological qualities. Even when manufactured with the utmost skill and care and apparently in a perfectly uniform manner arsphenamin and especially neoarsphenamin, prepared in different laboratories as well as different batches in the same laboratory, are apt to vary in toxicity and therapeutic activity. From the standpoint of physical appearance the products may be quite excellent and acceptable and yet produce annoying or even serious untoward effects when administered to human beings. Some of these effects may be unavoidable, even when the technic of administration is perfect; for example, arsphenamin itself is hemotecic even in isotonic solutions and the effects of intravascular hemolysis may be apparent in some cases by producing the non specific protein type of reaction. Furthermore, a perfectly good compound may produce Jarisch-Herxheimer reactions which are not to be ascribed to a toxic medicament although the reaction may be erroneously regarded as a toxicological effect.

Not infrequently and indeed usually, rigid tests for toxicity in rats and rabbits may fail to detect the presence of the toxic substances, because of a difference in reaction between these healthy lower animals and sick human beings and chemical analyses of the products are notoriously deficient for detecting and identifying impurities that may be held responsible. Nevertheless, there can be no doubt that toxic substances may be present in the medicament responsible for some of the untoward effects even though these cannot be identified with certainty by the biological and chemical tests in present use.

However, it should be stated that the manufacture of arsphenamin and neoarsphenamin has been brought to such a state of perfection that products fulfilling the toxicity standards of the Hygienic Laboratory are not usually to be held responsible for untoward toxic effects, although it is possible that impurities may gain access during manufacture which escape detection in animal tests and chemical assays. In my opinion these impurities are chiefly arsenical substances, since the toxicological reactions present the lesions and symptoms of arsenical poisoning. Furthermore, individual ampules of arsphenamin and especially of neoarsphenamin may acquire toxicity after leaving the manufacturer by reason of oxidation or other changes of deterioration which always renders advisable the routine use of fresh neoarsphenamin; here again I believe that these toxic substances are arsenical compounds rather than the methyl alcohol, sulphur compounds, etc., that are usually present in varying amounts.

As would be expected, susceptibility to the effects of these toxic arsenical substances as well as to the normal oxidation or reduction products of the organic arsenical compounds formed in the body after administration, varies among different individuals so that many factors relating to the patient require consideration. Fear and nervousness, the existence of general debility or some other disease and especially of the gastrointestinal tract and liver, defective elimination of arsenic as a result of disease of the liver, kidneys or both, congenital or natural allergic hypersensitiveness, focal

infections, etc., are some of the factors usually requiring consideration in arriving at conclusions regarding the etiology of a toxicological reaction in any given case or group of cases.

Finally, the untoward toxic effects of arsphenamin, neoarsphenamin and other organic compounds of arsenic may be due to factors concerned in the preparation and administration of the drugs. This is especially true of arsphenamin, because solutions of the drug require alkalinization or, at least, neutralization before intravenous injection and because faults in this part of the technic as well as over alkalinization and faults in the degree of dilution and rapidity of injection may bring about acute reactions in the blood. It was quite the custom of Ehrlich to blame the toxic reactions of arsphenamin upon faults in its administration, and present-day manufacturers are likewise liable to think first of some error in administration on the part of the physician when reactions follow the administration of their products; but such are not always the case.

It is apparent, therefore, that the toxic or untoward reactions following the administration of arsphenamin and its substitutes may be due to three primary factors, namely, (*a*) to the drug itself or some impurity it may contain; (*b*) to pathological states in the individual and variations from the normal in susceptibility to the toxic effects of the drugs and impurities and (*c*) to errors in administration. Of these three general causes, I believe that the most frequent and important are those due to factors involving the individual patient followed second in importance and frequency, by errors in the technic of administration and lastly, the toxicity of the arsenical derivatives produced in the body from the drugs themselves or to toxic arsenical compounds or other impurities gaining access to the drug before or during its administration.

The following summary of these various causes of the toxicological reactions that may follow the administration and especially the intravenous injection of the organic arsenical compounds shows how complicated the subject may be and many of these factors are worthy of more detailed discussion before the lesions, symptoms and treatment of the untoward reactions themselves are considered.

CLASSIFICATION OF CAUSES OF TOXICOLOGICAL REACTIONS FOLLOWING THE ADMINISTRATION OF ARSPHENAMIN AND NEOARSPHENAMIN

1. Due Primarily to the Drug
   1. Due to toxic physical properties of solutions.
   2. Production of agglutination of erythrocytes and precipitation of plasma constituents.
   3. Production of hemolysis.
   4. Toxic chemical effects of arsenical oxidation or reduction compounds.
   5. Toxic chemical effects of arsenic.
   6. Toxic chemical effects of non-arsenical impurities.

2. Due Primarily to the Patient
   1. Fear and nervousness.
   2. Endocrine disturbances; vagatonia.
   3. Focal infections.
   4. Pathological changes due to syphilis.
   5. Production of Jarisch-Herxheimer reactions.
   6. Production of syphilitic recurrences.
   7. Pathological changes due to non-syphilitic diseases.
   8. Pathological changes due to mercury.
   9. Natural or acquired hypersensitiveness to arsenical compounds.

3. Due Primarily to Method of Administration	1. Failure to neutralize solutions of arsphenamin. 2. Over-alkalinization of solutions of arsphenamin. 3. The use of defective water or saline for preparing solutions. 4. Excessive dilution. 5. The intravenous injection of too concentrated solutions. 6. Too rapid intravenous injection. 7. Oxidation and other physical and chemical changes in solutions. 8. The use of new rubber tubing. 9. Emboli of undissolved drug, cotton, air, etc. 10. Accidental injection of perivascular tissues.

Clinical Classification of the Toxic Reactions Following the Administration of Arsphenamin, Neoarsphenamin and Other Organic Arsenical Compounds.—With so many possible causes for toxic reactions following the administration of arsphenamin and its substitutes, it is no wonder that the lesions and symptoms may be many and very diverse in character and severity. Indeed, there seems to be an almost endless variety of symptoms that may be observed in different cases and the best one can do is to discuss certain types of reactions realizing at the outset that individual patients may show many deviations due to intrinsic factors concerning the particular drug used, its preparation and administration, not to mention the tremendous influence that may be exerted by the general condition of the patient at the time of administration.

In 1916, Schamberg, Raiziss and I[2] proposed a classification of the symptoms according to the time of onset after injection into immediate, early and late groups; since then various additional classifications have been proposed by Sicard and Roger,[3] Martin,[4] Fraser[5] and others, but I propose the following as being quite serviceable:

CLINICAL CLASSIFICATION OF TOXIC REACTIONS FOLLOWING INTRAVENOUS INJECTIONS OF ARSPHENAMIN AND ITS SUBSTITUTES

1. Immediate Reactions (During or Immediately after Injection)	1. The acute physico-hemoclastic reaction. 2. The acute vasoparetic reaction or "nitritoid crisis" (*a*) Mild. (*b*) Severe.
2. Early Reactions (Following within 24 Hours after Injection)	1. The gastro-intestinal reaction. 2. The protein and colloidal shock reaction. 3. The accidents of injection as phlebitis, thrombosis, perivascular infiltrations, etc.
3. Late Reactions (Occurring One Day to Several Weeks after Injection)	1. Hemorrhagic encephalitis. 2. Dermatitis and allied reactions. 3. Neuritis, neuro-recurrences and neural Herxheimer reactions. 4. Jaundice.

The etiology, lesions, symptoms and treatment of these various syndromes are discussed in Chapter LI, as likewise the few mild untoward effects that may commonly accompany any intravenous injection due to nervousness and fear on the part of the patient and not to toxic effects of the drug administered.

Frequency of Reactions Following the Administration of Arsphenamin and Its Substitutes.—It is not possible to express in accurate terms the frequency of all reactions following the administration of arsphenamin, neoarsphenamin and other organic arsenical compounds employed in the treatment

of syphilis. So many factors may be concerned, referable not only to the toxicity of the different drugs themselves but also to the skill and experience of the physician in preparing and injecting the solutions, that the incidence of reactions is subject to wide and varying fluctuations. However, I believe that it may be stated that the incidence is much higher for arsphenamin than for neoarsphenamin and with both drugs is generally lower at the present time than five to ten years ago, due to an increasing knowledge of the mechanism of the reactions and means for their prevention.

Influence of the Kind of Organic Arsenical Compound Administered upon the Incidence of Toxic Reactions.—At the present time arsphenamin, neoarsphenamin and sulpharsphenamin are being mostly employed in the treatment of syphilis. In regard to toxic reactions it may be stated that in the majority of cases they do not occur at all when the compounds are administered in the usual doses and by technically acceptable methods. This is especially true of the better brands of neoarsphenamin; arsphenamin produces more reactions, not only on account of its higher arsenic content but also because of toxic physical factors involving the solutions, the greater chances of producing agglutination and hemolysis of erythrocytes, the use of larger amounts of water, errors in the neutralization and alkalinization of the solutions, etc.

With present-day arsphenamin administered in dose of 0.4 to 0.6 gm. by intravenous injection to adults according to the technic described in Chapter LIX, the general incidence of reactions irrespective of sex, number of previous injections and stage of the disease and including such mild reactions as headache, nausea and diarrhea, is about 10 to 20 per cent. Neoarsphenamin in dose of 0.6 to 0.9 gm. by intravenous injection to adults according to the technic described in Chapter LIX, produces not more than 2 to 10 per cent. of reactions. In other words, the incidence of untoward reactions following the administration of arsphenamin has been in my experience at least 4 to 10 times higher than produced by neoarsphenamin; Ormsby has[6] reported an incidence of about 20 per cent. reactions following the administration of arsphenamin and about 8 per cent. after neoarsphenamin. Merritt[7] states that a reaction of some sort, although often slight, is to be expected in from one-third to one-fifth of all injections of neoarsphenamin, the incidence being still higher for arsphenamin. In dispensary practice the incidence is always likely to be higher than in private practice; for example, reactions of some sort (usually mild) occurred in 100 or 43 per cent. of 233 patients treated with arsphenamin in the clinic of Dr. Schamberg and in 486 or 39 per cent. of 1217 patients treated with neoarsphenamin. These figures are based almost entirely upon the reports of patients upon the occurrence of fever, chills, headache, nausea, vomiting or diarrhea after injection; not infrequently the only symptom reported was headache which obviously may have been due to some other factor. In other words these figures are certainly too high for the true incidence of reactions since symptoms of the kind reported may not have been due to the drugs at all. As reported, however, by these adult dispensary patients, the incidence of the various symptoms were as follows, there being but slight differences in the incidences of reactions in both sexes:

	Headache (Per Cent.)	Nausea (Per Cent.)	Vomiting (Per Cent.)	Diarrhea (Per Cent.)	Fever (Per Cent.)	Chilliness (Per Cent.)
Arsphenamin.....	60–70	46–54	14–26	36–50	30–40	38–40
Neoarsphenamin...	64	50–68	20–25	37–39	27–31	24–28

Sulpharsphenamin administered by subcutaneous, intramuscular and intravenous injection has produced in my practice a higher incidence of dermatitis than either arsphenamin or neoarsphenamin, although I have not administered this compound to a sufficient number of cases to express even an approximate estimate of the incidence of this and other toxic reactions.

As stated in Chapter LI, the incidence of the severer reactions as exfoliative dermatitis, jaundice and the so-called hemorrhagic encephalitis is much lower. Sulpharsphenamin, like arsenophenylglycin, is somewhat more likely to produce dermatitis than arsphenamin and neoarsphenamin, although the products marketed during the past two years have been in my experience much less toxic in this regard than those formerly prepared. The incidence of jaundice has fluctuated greatly in different years due, presumably, according to Stokes and others, to the fact that jaundice may be caused by co-incident infections rather than by the drug. Fatal cases of hemorrhagic encephalitis have been quite rare in America; most cases on record have occurred in Europe.

Furthermore, the incidence of reactions varies considerably according to the brand of arsphenamin and neoarsphenamin administered and, indeed, may vary with different lots of the same compound prepared by the same laboratory. There is no uniformity at all in the experience of physicians with these compounds; some observe a high incidence of toxic reactions with one brand which the physician next door may be using in approximately the same dosage with very few reactions. It is well nigh a hopeless task even to try to reconcile or offer an explanation of the remarkable variations in toxic reactions due to these compounds in the experience of different physicians, because of the large number of factors requiring consideration, but dosage and technic of administration are of more importance than the brand of arsenical employed.

Influence of Dosage upon the Incidence of Toxic Reactions.—Needless to state the incidence of toxic reactions is greatly influenced by dosage. For example, the administration of 0.1 to 0.3 gm. of arsphenamin or 0.2 to 0.4 gm. of neoarsphenamin are only occasionally followed by reactions and not infrequently the absence or low incidence of toxic reactions in the practice of some physicians is found upon inquiry to be due to the fact that they are injecting smaller doses than generally employed and under these circumstances, together with the use of good methods for preparing and administering solutions of the drugs, it is not difficult to understand how or why untoward effects are seldom observed.

Undoubtedly the subject of dosage has not received the attention that its importance demands in relation to the treatment of syphilis and more especially in relation to the toxic reactions. Too many physicians administer arsphenamin and neoarsphenamin by rule instead of gauging dosage and intervals of injection according to the condition of each individual patient. In the treatment of acute early syphilis of otherwise healthy vigorous subjects, the usual maximum doses of 0.6 gm. arsphenamin and 0.9 gm. neoarsphenamin are indicated but in the treatment of chronic syphilis the condition of the kidneys, liver, cardio-vascular system, etc., must be taken into account. It appears that most of the fatalities ascribed to arsphenamin and its substitutes have occurred among individuals with advanced pathological changes in the internal organs to whom the drugs should not have been given at all or in but small and cautious doses. Indeed, the salvarsan committee of the Allgemeiner aerztlicker Verein of Munich went so far in 1920 as to recommend that manufacturers should not be allowed to place more than 0.6 gm. of neoarsphenamin in a tube as representing the maximum

single dose to be given at one time, since in their analysis of fatalities it was found that the incidence rose sharply with larger doses. However, this point should not be over-emphasized; as shown by Wechselmann, a dose of 0.1 or 0.2 gm. of arsphenamin may be dangerous for some individuals and especially in the presence of nephritis whereas 0.6 gm. is safe for the majority. In other words, the question of dosage bears a very important relation to the question of individual susceptibility and tolerance which is discussed with more detail in Chapter XLVII.

Influence of Dosage upon the Toxicity of Arsphenamin and Neoarsphenamin for Rats.—As would be expected, the resistance of rats to the effects of arsphenamin and neoarsphenamin likewise varies greatly according to the amounts administered per kilogram of body weight. Individual variations in resistance among these animals have been noted similar to individual variations among human beings, but by keeping the animals on a uniform diet, avoiding the injection of pregnant females and selecting animals of nearly uniform age and weight it is possible to bring out rather sharply the influence of dosage upon the incidence of fatal toxic reactions. An analysis of my records covering toxicity tests of 181 different lots of arsphenamin and 278 lots of neoarsphenamin conducted several years ago have shown the following results; the great majority of animals were of the regulation weight (100 to 150 grams) with a few about 90 grams and a few as high as 170 grams. The injections were intravenous and the general technic exactly as described in Chapter II.

	Arsphenamin	Neoarsphenamin
Average highest dose per kilo killing at once	0.150	0.367
Average highest dose surviving for 1 day	0.133	0.343
Average highest dose surviving for 2 days	0.129	0.340
Average highest dose surviving for 5 days	0.128	0.318
Average highest dose surviving for 7 days	0.128	0.317
Average highest dose surviving for 10 days	0.128	0.316
Average highest dose surviving for 14 days	0.127	0.315

It will be noted that with arsphenamin the highest percentage of deaths occurs in the first forty eight hours after injection and after this time the percentage of survivals remains quite constant; with neoarsphenamin however, the highest percentage of deaths is not reached until 5 to 10 days after injection. These results are in confirmation of those observed by Lake and Roth in the Hygienic Laboratory and support the statements of this laboratory that in toxicity tests of arsphenamin the results may be evaluated at the end of 48 hours whereas in tests with neoarsphenamin a period of at least 5 to 7 days must elapse after injection.

Influence of Sex upon the Incidence of Toxic Reactions.—Women are more likely to develop reactions than men. In my experience the mild reactions of nausea, headache, fever, diarrhea, etc., following injections of arsphenamin are as 5:4 as compared to men and similar reactions after injections of neoarsphenamin are almost 2:1 as compared with the incidence among men. These differences are probably due to the fact that, although women as a group exhibit less fear and nervousness concerning the operation of injection, yet their nervous systems are more susceptible to shocks and they are likewise more subject to endocrine disturbances, constipation and other predisposing causes. The incidence of jaundice is somewhat higher among

women than men due in part at least to the commonly observed fact that the incidence of cholelithiasis and various disorders of the liver and bile ducts is higher among them than among men.

The incidence of fatalities following injections of arsphenamin and its substitutes has been, however, higher among men, but this is probably due to the fact that more men than women undergo treatment for syphilis. However, while women tend to develop the minor toxic reactions more frequently than men as stated above, it may be that they are actually somewhat more resistant to the severer toxic reactions. In this connection the results of my toxicity tests with male and non-pregnant female rats are not without interest:

In determining the toxicity of 71 different lots of arsphenamin, 185 male and 175 non-pregnant female rats of regulation weight were employed. The dose injected intravenously was 0.100 per kilo as described in Chapter II. Among the males there was 76 per cent. survivals for two days and among the females, 85 per cent. survivals.

In toxicity tests of 66 different lots of neoarsphenamin, 242 male and 173 non-pregnant female rats were injected intravenously with 0.200 gm. per kilo of weight; 79 per cent. of the males survived for 7 days while 84 per cent. of the females survived.

These results have shown, therefore, that non-pregnant female rats are somewhat more resistant to the toxic effects of arsphenamin and neoarsphenamin than male rats of the same weight, kept under the same conditions and injected in exactly the same manner at the same time; I believe that the same conditions pertain to human beings in that in a broad and general manner women are more resistant to the severer toxic reactions of arsenic than men.

Influence of the Number of Injections upon the Incidence of Reactions.—In my experience the incidence of reactions is generally higher after five or more injections of arsphenamin or neoarsphenamin have been given than after the first injection. Ormsby however, states that in his experience the incidence following the administration of neoarsphenamin, has been higher after the first injection and Leredde in 1914 pointed out that most of the reported fatalities ascribed to salvarsan occurred after the first injection because Jarisch-Herxheimer reactions are more likely to occur after the first than after subsequent injections. In my experience however, there is likewise a greater tendency for reactions during the second or subsequent "courses" of injections of arsphenamin and neoarsphenamin than during the first course.

It is highly probable that these effects are due to the accumulation of arsenic in the liver and other organs or to the production of tissue injuries resulting in interference with the metabolism and elimination of the compounds as treatment progresses. In some cases it is also apparently due to the acquisition of allergic sensitiveness to the drugs. In those rare instances of natural allergy to arsenic the first injection may of course produce more reaction than subsequent injections if a continuation of treatment with the same compound is attempted. One may also consider the possibility of more reaction from the first than from subsequent administrations due to the sudden destruction of large numbers of spirochetes with the production of toxic disintegration substances, but I believe this factor is far over-rated in importance.

Cumulative toxic effects due to the retention of arsenic as treatments are continued along with the possibility of these lowering general resistance to bacterial infections by histological changes in the bone marrow and other organs as well as by tissue changes in the liver, kidneys, etc., are more likely to be responsible for toxic reactions and especially the severer ones as dermatitis and hepatitis.

Influence of Age and Weight upon the Incidence of Toxic Reactions.—It is now well known that children bear the administration of arsphenamin and its substitutes in doses according to body weight much better than adults;

the same is true of the inorganic compounds. Even in 1786 Fowler[8] stated in his original monograph on the use of his solution, that "I observed that children were less apt to suffer from the medicine than adults."

This increased tolerance of children to arsenic is possibly due to several factors. In the first place the studies of Benedict[9] and of Benedict and Talbot[10] have shown that the metabolic rate of young animals is greater than that of old animals since the active mass of protoplasm which determines fundamental metabolism decreases with advancing age. Moreover, the blood volume decreases with advancing age and these two factors apparently reduce the facility of older animals for getting rid of toxic substances. In addition very young children are usually treated with intramuscular injections of the arsenicals which are less apt to produce toxic reactions than intravenous injections. Furthermore, children are usually in better general physical condition and free of predisposing states to toxic reactions as vagatonia, constipation, focal infections, hepatic and renal disorders, etc.

Influence of Age and Weight upon the Resistance of Rats to Arsenical Compounds.—Exactly similar conditions have been observed in rats treated with intravenous injections of various arsenical compounds, that is, young rats are more resistant than older animals. A few years ago it was shown by Roth[11] in experiments with white rats injected intravenously with arsphenamin and neoarsphenamin, that young rats are much more resistant than old and heavier animals. For example, of rats below regulation weight (50 to 100 grams) injected intravenously with 0.140 gm. of disodium arsphenamin per kilogram of weight, 53 per cent. survived for forty-eight hours; of rats weighing from 100 to 150 grams (regulation weights), 28 per cent. survived, whereas in one series of rats much above regulation weight (180 to 275 grams) none survived. Similar results were observed with neoarsphenamin since 82 per cent. of young rats weighing from 42 to 70 grams survived for seven days or longer the intravenous injection of 0.240 gm. per kilogram of body weight whereas only 67 per cent. of older rats of regulation weight (101 to 135 grams) survived.

An analysis of my records of toxicity tests with arsphenamin and neoarsphenamin, conducted as described in Chapter II, have shown similar results. For example, in testing 100 different lots of arsphenamin 526 rats were injected intravenously with 0.100 gm. per kilogram of weight. Of the animals weighing from 90 to 125 grams, the survivals for two days was 72 per cent.; of the animals weighing from 130 to 150 grams the survivals was 71 per cent., while among slightly heavier animals weighing from 160 to 180 grams the survivals was 58 per cent. In tests of 105 different lots of neoarsphenamin 592 rats were injected intravenously with 0.200 gm. per kilogram of weight. Of the animals weighing from 90 to 125 grams, the percentage of survivals for 7 days was 82 per cent.; of the animals weighing from 130 to 190 grams, the survivals was 78 per cent.

Hammett and Nowrey[12] have observed a still more striking influence of the age of rats upon resistance to injections of arsenic trioxid. For example, among rats 60 to 90 days old and weighing from 100 to 137 grams, the fatal dose was 0.0011 gm. or over per kilogram of weight; among rats 120 to 150 days of age and weighing from 124 to 175 grams, the fatal dose was 0.009 gm. per kilo; while among rats 210 to 240 days of age and weighing from 161 to 223 grams, the fatal dose was 0.008 gm. per kilo of weight showing a progressive decrease in resistance with advancing age. Hammett and Nowbrey ascribe the results in large part to differences in metabolic rates, pointing out that the mass of active protoplasm concerned in getting rid of noxious agents decreases with advancing age and calling attention to the observations of Donaldson[13] and Jackson[14] that the viscera decrease in their percentage relation to body weight with advancing age.

Incidence of Fatalities Ascribed to the Administration of Arsphenamin and Neoarsphenamin.—Since the introduction of salvarsan for the treatment of syphilis in 1910 by Ehrlich, millions of doses have been administered without serious mishaps. When one pauses to consider the potential dangers connected with its administration by the thousands of physicians the world over and especially the accidental injection of acid solutions and likewise the fact that thousands of individuals with advanced heart and kidney disease as well as numerous cases in extreme states of debility due to syphilis or other pathological states have been injected almost indiscriminately, the wonder is not that fatalities have occurred but that the incidence is so low in comparison to the number of injections given.

In 1913 Leredde[15] states that the deaths from salvarsan were approximately as follows:

1910	50,000 injections—16 deaths	(1:3000)
1911	800,000 injections—92 deaths	(1:8700)
1912	1,280,000 injections—66 deaths	(1:19000)
1913	2,000,000 injections—37 deaths	(1:54000)

These figures were interpreted as indicating that a large proportion of deaths were due to faulty technic in administration and disregard of contraindications, rather than to toxicity of the drug, since the incidence decreased as experience with it was gained. Arranged according to the number of injections received by the patient, the table shows that of 211 cases:

104 occurred after the 1st injection
55 occurred after the 2nd injection
13 occurred after the 3rd injection
8 occurred after the 4th injection
1 occurred after the 5th injection
1 occurred after the 6th injection
1 occurred after the 7th injection

The decrease of fatalities after the first injection, without a comparable decrease after the second injection, was ascribed by Leredde to the fact that Herxheimer reactions were responsible for many fatalities and that it occurs most frequently at that time.

The total of reported fatalities following injections of salvarsan up to 1914 was approximately 274 cases; in Schmitt's[16] analysis of these, it was found that in a large proportion there was no connection between the drug and the fatalities, while in others the dosage was excessive. Benario[17] goes further and states that of these 274 cases only from 4 to 6 could be ascribed to salvarsan given by a proper technic. In the 41 cases in which the drug had been given to non-syphilitics, the authors almost invariably state that the patient was dying of advanced heart or liver disease and that salvarsan had been given as a last resource.

At about this time, Wechselmann[18] published his little book on the pathogenesis of salvarsan fatalities, which made a profound impression in view of his extensive experience with the drug, with only one death occurring in a young girl who had received 0.1 and 0.2 gm. of salvarsan. Wechselmann attributed this fatality to defective elimination, the result of preceding mercurial treatment. According to his analysis, only the smallest number of fatalities could be attributed directly to salvarsan and, while he was unable to offer a uniform explanation fitting all cases, he was of the opinion that the simultaneous or preceding administration of mercury was particularly dangerous from the standpoint of injury of the kidneys resulting in deficient elimination of the drug with the consequent production of the highly toxic oxidation products of which "arsenoxid" was the type.

The most valuable recent analysis of fatalities has been published by Meirowsky,[19] acting as secretary of a committee appointed by the Allgemeiner aerztlicher Verein of Cologne to investigate the subject. This report deals with 13,000 injections of old salvarsan, 40,954 of sodium salvarsan, 171,826 of neosalvarsan and 64,500 of silver salvarsan. The chances of fatal reactions were estimated as follows:

The Committee found that when the dose of neosalvarsan exceeded 0.6 gm. the deaths rose to 1 to 3000 and hence recommended that 0.6 gm. be the maximum dose.

1 in 13,000 injections of old salvarsan
1 in 20,000 injections of sodium salvarsan
1 in 162,800 injections of neosalvarsan

One case of jaundice was recorded for each 5000 injections: one in 2000 for old salvarsan and one in 6000 for neosalvarsan. Injury of the skin was recorded in 48 cases, including five that terminated fatally. Arndt[20] states that during 1921 there were 14,991 injections of salvarsan given in his clinic to 1913 patients. Twelve deaths occurred or about 1 to every 1250 injections: 1 of hemorrhagic encephalitis, 1 of myelitis, 3 of dermatitis and 7 of acute or subacute yellow atrophy of the liver. Certainly this was a much higher death rate than usual and suggestive of the use of a rather highly toxic brand of salvarsan.

These reports show, however, that neoarsphenamin is much safer than arsphenamin, a conclusion well substantiated by experience. In the United States the incidence of fatalities has dropped since 1918, owing to the greater use of neoarsphenamin. As previously stated, the wonder is that the incidence of fatalities from injections of arsphenamin and its substitutes is as low as reported, there being approximately 600 recorded cases, although it is to be kept in mind that not all fatalities have been reported by any means, and especially those due to errors in administration. I personally know of several due to the accidental administration of concentrated acid solutions of arsphenamin given in mistake for neoarsphenamin and sulpharsphenamin and have heard of additional cases, that have not been recorded. But, excluding fatalities due to this grievous error, the incidence is indeed very low and apparently most have been due to two factors, namely, (*a*) errors in the technic of administration and (*b*) an unwise disregard of contraindications; both subjects are of extreme practical importance and are discussed with more detail in following chapters. Not infrequently the suggestion is made that fatalities are hushed up by arsphenamin enthusiasts and that Ehrlich and other German physicians have made strenuous and persistent efforts to blame these deaths upon everything but the drug and particularly upon errors in technic of administration, pathological states of the patients, etc., but I do not agree with statements of this sort. It is quite clear, when one refers to an "injection of arsphenamin," that this loose expression implies more than the drug alone, since it consists of other possible toxic factors as the water employed, sodium chlorid, sodium hydrate, bacteria or their disintegration products, etc.

Comparative Rapidity of Fatal Toxic Reactions from Arsphenamin and Neoarsphenamin in Rats.—As previously stated, the toxic effects of arsphenamin upon the rat are much more rapid than in the case of neoarsphenamin. For this reason, the Hygienic Laboratory has ruled that in the official toxicity tests the results may be evaluated at the end of forty-eight hours after injection in the case of arsphenamin, but not until the end of seven days in the case of neoarsphenamin. In addition to the figures which I have already quoted above from an analysis of my records of toxicity tests with rats, the following percentages of fatal reactions after the intravenous injection of 201 different lots of arsphenamin in dose of 0.100 gm. per kilo (1042 rats), and of 280 different lots of neoarsphenamin in dose of 0.200 gm. per kilo (1585 rats), may not be without some intreest in relation to the comparative rapidity of fatal reactions after the injection of these compounds, the technic employed being exactly as described in Chapter II:

	Arsphenamin	Neoarsphenamin
Percentage succumbing at once	11.1	0.6
Percentage succumbing in 24 hours	15.4	3.2
Percentage succumbing in 48 hours	3.2	1.9
Percentage succumbing in 72 hours	0.5	4.2
Percentage succumbing in 5 to 7 days	2.3	17.6
Percentage succumbing in 8 to 10 days	2.3	4.4
Percentage succumbing in 11 to 14 days	2.2	2.9
Percentage surviving more than 14 days	63	65.2

In other words, from 35 to 37 per cent. of rats injected intravenously with 0.100 gm. disodium arsphenamin and 0.200 gm. neoarsphenamin per kilo succumbed within 14 days after injection, but in the case of arsphenamin approximately 30 per cent. of these deaths occurred within the first forty-eight hours after injection, whereas with neoarsphenamin only 5.7 per cent. of deaths occurred in this time; on the other hand, at the end of seven days the deaths among the rats receiving arsphenamin was 32.5 per cent. and among those receiving neoarsphenamin approximately 27.5 per cent., showing that arsphenamin is more rapidly toxic than neoarsphenamin under well controlled experimental conditions.

CHAPTER XLV

PHYSICOCHEMICAL CAUSES OF TOXIC REACTIONS PRODUCED BY ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

With this brief survey and summary of the numerous possible causes and clinical varieties of the toxic reactions that may follow the administration of arsphenamin neoarsphenamin and other organic arsenical compounds in the treatment of syphilis and other diseases, it is now advisable to discuss with more detail the nature and mechanism of the causes insofar as present knowledge permits, because a good understanding of these enables the physician to treat toxic reactions more successfully and what is more important, to exercise proper precautions for their prevention. Since the immediate and early untoward effects are frequently due to physicochemical factors and changes in solutions of the drugs injected intravenously, it is logical to discuss these first.

Physical Chemistry of Arsphenamin and Neoarsphenamin in Relation to Toxic Reactions.—It is now generally believed that solutions of arsphenamin hydrochlorid (acid solutions) as well as alkaline solutions of the compound (disodium salt) and solutions of neoarsphenamin possess well-marked colloidal properties and that various physical conditions may influence the

colloidal or physical chemistry of these solutions. In 1914 Fleig[1] pointed out that the physical state of the solutions, in particular their clearness, varied with the amount of sodium hydroxid and sodium chlorid present, an insufficient amount of the former with an excess of the latter producing a distinct turbidity, which he explained as being due to a precipitation of the arsphenamin base. Clinical experience and animal toxicity tests have shown me that such solutions of either disodium arsphenamin or neoarsphenamin are of increased toxicity and much more likely to produce early "nitritoid" reactions.

Hugo Bauer[2] investigated the colloidal properties of silver and sodium salvarsans, collargol and atoxyl, and concluded that they belong to the class of semi-colloids, the sizes of the particles being such as represent the dividing line between the colloids and crystalloids. Silver arsphenamin, he claims, is a chemically uniform substance with the silver existing in a complex combination with arsphenamin and not merely as mechanically admixed colloid.

Raiziss and Gavron,[3] after thoroughly investigating the colloidal properties of arsphenamin and neoarsphenamin, reached the conclusion that solutions of both in water had colloidal properties, the former behaving like a reversible colloid since when once precipitated from solution, it can be redissolved into a colloidal solution in contradistinction to the proteins and various colloidal metals which are irreversible colloids. They also observed that in solutions of silver and gold arsphenamin the metals did not diffuse as stated by Bauer, which indicates that either the metals are combined to the arsenic or nitrogen and split off during diffusion, or, as they believe, that these compounds are not homogenous combinations but mixtures of sodium arsphenamin and colloidal metals.

The investigations of Klemensiewicz[4] upon the viscosity of aqueous solutions of arsphenamin have likewise indicated their colloidal nature. He observed that the viscosity increased with the concentration of the solutions and reached the conclusion that arsphenamin is to be classed among the "lyophiles" or "emulsoids" and that the increase in viscosity is due to polymerization of the compound. Recently Voegtlin, Johnson and Dyer[5] have shown that this question of viscosity of acid and alkaline solutions of arsphenamin bears a relation to toxicity for rats and in searching for an explanation of the differences in viscosity in relation to the toxicity of arsphenamins prepared by different methods by manufacturers, concluded that the method of precipitation employed (by ether from a methyl alcohol solution of the drug or fairly concentrated hydrochloric acid from an aqueous solution) largely determined the solubility, viscosity and toxicity of arsphenamin hydrochlorid, the method of precipitation of the drug by ether from methyl alcohol solution yielding products more readily soluble and of lower viscosity than lots prepared by precipitation by hydrochloric acid. At any rate these investigations have suggested that important physico-chemical changes may occur in solutions of arsphenamin without involving any oxidative changes which bear an important relation to toxicity. Voegtlin and his associates have suggested that the decrease in toxicity of solutions accompanying the decrease in viscosity are due essentially to dispersion of the particles in solution, thereby reducing the power of such solutions to enter into reactions with the colloidal constituents of the blood. In this respect they believe that arsphenamin acts like an amphoteric colloid and the results have indicated from a different angle that the toxicity of arsphenamin is subject to great changes according to the manner in which the drug is prepared for injection; the results have also emphasized the necessity for preparing solutions in an absolutely uniform manner for biological testing as previously discussed in Chapter II, as well as the importance of technic in the administration of the drug by intravenous injection to human beings, which is discussed with more detail in Chapter XLVIII.

While the colloidal state of solutions of arsphenamin may, therefore, have a direct bearing upon their toxicity, it would appear that even more important changes in the physical colloidal state of these may occur after intravenous injection and that additional toxic agencies may be brought into play by a disturbance of the colloidal equilibrium of the plasma. For example, Danysz[6] believes that a short time after the intravenous injection of solutions of the disodium salt of arsphenamin that the sodium combines with the free carbonic acid of the plasma, forming soluble carbonate while leaving a precipitate of the insoluble base and that the remainder of the mono or disodium salt, combining with the calcium phosphates, also produces an insoluble compound. I shall later in this chapter refer again to this theory, but here it may be mentioned that Dale[7] points out that alkaline solutions of

arsphenamin are practically insoluble at the pH of the blood, and must therefore circulate in a colloidal form, aggregation of the particles being prevented by the plasma proteins. Furthermore, the Salvarsan Committee of the British Medical Research Committee have expressed a similar view in these words: "There is a good deal of evidence in support of the view that the varying toxicity of different samples of '606' is related to small differences in the physical properties of the product, which determine the state of physical dispersion in which the free base comes out of solution when the alkaline solution is injected intravenously." What the evidence for this view is, was not very fully stated. An instance is cited, however, in which samples of arsphenamin dissolved in tap-water caused symptoms of vasomotor disturbances, whereas, when dissolved in distilled water no symptoms resulted, while other samples could be dissolved in tap-water with impunity. The Committee concluded: "It would be very difficult to reconcile such an experience with the view that abnormal toxicity depends on the presence of an undue proportion of more toxic by-products," which leads to the inference that physical factors were held chiefly responsible for the varying toxicity.

Hunt[8] has also observed, with certain lots of arsphenamin, phenomena which strongly supports the idea that the physical condition (colloidal?) of the solution or the presence of a very labile toxic compound may at times account for untoward reactions. He has found that some preparations of arsphenamin are very toxic when the solutions are prepared at ordinary room temperature, and that the toxicity is greatly reduced by moderate heating or by allowing the solutions to stand for a time at room temperature; Hunt suggests that these changes in toxicity may be due to a simultaneous change in the physical state of the solution.

It is practically certain that hemolysis and agglutination of erythrocytes by solutions of arsphenamin are colloidal phenomena and when occurring intravascularly may lead to the production of toxic reactions largely due to altered proteins and pulmonary embolism. In other words, the colloidal nature of arsphenamin and neoarsphenamin may result in the production of toxic reactions *per se* when injected intravenously or, more importantly, bring about the production of disturbances in the colloidal equilibrium of the plasma and under certain circumstances such physical (colloidal?) reactions as intravascular agglutination and precipitation, with consequent toxic reactions.

However, before leaving the present subject brief reference may be made to the investigations of Elvove and Clark[8a] upon the acid-base equilibria of arsphenamin solutions, and especially in relation to the alkalinization of arsphenamin solutions for administration. Obvious errors were found in the usual indicator methods of measuring pH values, but hydrogen electrode measurements gave reproducible and better data which were confirmed by the rate of hydrolysis of methyl acetate. This method however, is not adaptable for clinical use, although the authors believe that alizarin yellow R may be used as an indicator for checking correct alkalinization of arsphenamin solutions if there are reasons for suspecting that the normal solution of sodium hydroxid employed for this purpose may be defective. Hunter and Patrick[8b] have also studied the isoelectric point by conductivity measurements in relation to the physical and colloidal nature of arsphenamin, and offer an explanation for the abnormalities found in conductivity measurements in different solutions which is based upon McBains' conception of an ionic micelle found in solutions of colloidal electrolytes and offering a possible explanation for the differences between the toxicities of acid and alkaline solutions.

Hemolysis by the Organic Arsenical Compounds in Relation to Toxic Reactions.—Among the possible physical causes for toxic reactions following the intravenous injection of arsphenamin and its substitutes, that of intravascular hemolysis may be discussed, not only because the drugs themselves may be hemolytic under certain conditions but also because of the possibility of hemolysis by hypotonic solutions if water is employed for preparing the solutions and, in the case of arsphenamin, by the presence of an excess of acids or alkali as well.

In 1920, Schamberg, Raiziss, Weiss and myself[9] briefly reported that both acid and alkaline solutions of arsphenamin in water or saline solution were hemolytic *in vitro*, and especially acid solutions. We also observed that 2- to 4-per cent. solutions of neoarsphenamin in water or saline solution were not ordinarily hemolytic *in vitro* although 0.5 per cent. solutions in water were hemolytic due to the hypotonic solution. Later Miss Yagle and myself[10] studied the hemolytic effects of arsphenamin and neoarsphenamin for *washed* erythrocytes *in vitro* more extensively and concluded that hemolysis by solutions of the disodium salt of arsphenamin was due more to solutions and excess of alkali than to the drug itself. In the case of neoarsphenamin, we found that solutions in saline were not ordinarily hemolytic although dilute solutions in water may be hemolytic due to the effects of hypotonic solutions. Subsequent investigations by Miss Richter and myself have shown that arsphenamin and sulpharsphenamin, are directly hemolytic *in vitro* for washed corpuscles although much less so for corpuscles in the presence of serum, as first shown by Crabtree[11] and amply confirmed by our experiments. Naturally the fact that arsphenamin and its substitutes are much less hemolytic in the presence of the plasma proteins *in vitro* greatly reduces the significance to be placed upon intravascular hemolysis as a cause for toxic reactions, but the protection may not be complete under certain conditions and the phenomenon both *in vitro* and *in vivo* is worthy of brief discussion in relation to toxic reactions.

Hemolytic Activity of Arsphenamin in Vitro.—(a) Solutions of arsphenamin in water without neutralization (*acid solutions;* pH about 4.6) are highly hemolytic for washed corpuscles and to a lesser extent for whole blood; in this case hemolysis may be ascribed to the acids, water and drug. Similar solutions in saline are much less hemolytic and especially for whole blood, because in the latter the plasma affords considerable protection of the corpuscles against the hemolytic activity of both acids and the drug itself and hemolysis by hypotonic solutions does not enter into consideration under these conditions.

(b) *Solutions of the monosodium salt of arsphenamin* (solutions neutralized with sodium hydroxid just to the point of neutralization and clearing) in *water* are hemolytic for *washed* corpuscles due primarily to the hemolytic activity of the hypotonic solution and secondarily to the drug. But hemolysis for *whole blood* is very much less than for washed corpuscles, because the plasma proteins protect the corpuscles against hemolysis by the drug as shown by Crabtree, and the salts of the plasma establish sufficient tonicity unless the proportions of solution to blood are excessive.

It may be said, therefore, that when a solution of the monosodium salt of arsphenamin in isotonic saline is administered by slow intravenous injection, permitting immediate dilution of the solution in the blood, that hemolysis is negligible or does not occur at all; certainly there is no reason for suspecting hemolysis under these conditions when saline solution is employed because the solution is isotonic, the acids are neutralized, there is no excess of sodium hydroxid and the corpuscles are protected by the plasma against the feeble hemolytic activity of the drug itself and traces of alkali. For these reasons solutions of the monosodium salt of arsphenamin are the least hemolytic of all and from this standpoint are the most desirable for intravenous injection.

(c) Solutions of the *disodium salt of arsphenamin* (usually containing about one-third excess of sodium hydroxid or about 0.9 c.c. of a normal solution per 0.1 gm. of drug and possessing a pH of about 9.9) are slightly more hemolytic for both washed corpuscles and whole blood than the solutions of monosodium arsphenamin, due to the excess of alkali. Dilute solutions in water (0.1 gm. per 20 c.c.) are slightly more hemolytic than similar solutions in saline.

Glucose affords no protection against hemolysis of human corpuscles *in vitro;* solutions of disodium arsphenamin in saline are just as hemolytic and solutions of the same in 1- to 5-per cent. solutions of glucose in saline.

Different lots and brands of arsphenamin are quite uniform in hemolytic activity when the solutions are prepared and tested in exactly the same manner. The corpuscles of different human beings may, however, show widely varying resistance to hemolysis by arsphenamin, but injections of arsphenamin and neoarsphenamin in the treatment of syphilis have no marked or constant effect in either increasing or decreasing resistance to hemolysis *in vitro*. These observations have been of special interest in relation to the occurrence of jaundice during treatment with arsphenamin and likewise in the treatment of non syphilitic anemia with arsphenamin to which further reference will be later made. If arsphenamin injections have any influence at all upon resistance of the corpuscles to hemolysis *in vitro*, the experiments made by Miss Richter and myself with syphilitic individuals under treatment, and with rabbits injected with therapeutic doses, indicate that after three to five doses at weekly intervals resistance is slightly lowered, followed later by restoration to the same resistance observed before treatment was given or possibly a very slightly increased resistance.

Crabtree has also made the interesting observation that the hemolytic activity of different samples of arsphenamin for washed corpuscles varied in a general way with their toxicity for rats, when the latter depended upon variations in the conditions of reduction of the nitro to the amino-group in the preparation of the drug. The hemolytic activity of different samples varied roughly, as did their toxicity for rats, but this was not constant or sensitive enough to be used as a substitute for the rat test for determining the toxicity of arsphenamin. Crabtree has also found that, on standing or shaking alkaline solutions of arsphenamin, the hemolytic activity for washed erythrocytes is decreased and may disappear altogether; also that solutions of m-amino-p-hydroxy-phenylarsenious oxid ("arsenoxid") are non-hemolytic; in other words the increased toxicity of "oxidized" solutions of arsphenamin are not to be ascribed to an increase of hemolytic activity. Crabtree also observed that warming a solution of disodium arsphenamin to 55°C. decreased its hemolytic activity and this is quite in agreement with the fact that solutions of arsphenamin prepared in hot water are not more toxic than solutions prepared with cold water. I have repeated these experiments and found essentially similar results; also that "oxidation" of solutions of disodium arsphenamin results in an even greater loss of agglutinative activity for human erythrocytes. Even the mere matter of allowing a solution to stand a few hours at room temperature may result in reducing agglutination without any change in hemolytic activity.

The exact mechanism of hemolysis by arsphenamin is not known; doubtless profound intracellular colloidal reactions occur resulting in a rupture of the cell with liberation of hemoglobin and solution of stroma. As shown by Crabtree, arsphenamin unites with washed corpuscles in the test-tube and if the solution is insufficient for producing hemolysis (1:5000) the corpuscles may be removed by centrifuging and when re-suspended in saline are found to possess an increased resistance to the hemolytic action of water or hypotonic saline solutions, as Gunn[12] has described for solutions of sodium arsenite and sodium arsenate. This increased resistance, however, only delays hemolysis and is not absolute and no increase of resistance was found to serum hemolytis by specific hemolysis and guinea-pig complement.

Of interest in connection with this antihemolytic activity of weak solutions of arsphenamin is the question of whether or not human corpuscles acquire an increased resistance to arsphenamin after preliminary exposure to weak solutions of the drug in relation to the possibility of changes of this kind occurring during the treatment of syphilis with intravenous injections of arsphenamin. I have observed that when washed human corpuscles are exposed to 1:5000 solutions in saline for an hour at 37°C. followed by centrifuging and resuspension in saline, that the "sensitized" corpuscles are, however, not any more resistant to hemolysis by arsphenamin than control suspensions. Similar effects were observed in relation to the agglutination of human corpuscles by arsphenamin, to which reference will be later made.

As previously stated, the presence of serum tends to protect corpuscles against the hemolytic activity of saline solutions and the disodium salt of arsphenamin; I have observed similar effects with other hydrophil colloids

as gelatin and acacia. The mechanism of this protection by colloids is not known but I surmise that it is the same as advanced by Oliver and his associates in explanation of the mechanism of protection of erythrocytes by these substances against the agglutinative activity of arsphenamin. According to this theory, arsphenamin is "bound" by the protective colloid as the proteins of the plasma and especially by the globulins, gelatin, acacia, etc., preventing the union of arsphenamin with the corpuscles as well as preventing agglutination. I believe that the same theory may be accepted in explanation of the protection afforded by the plasma proteins and gelatin against hemolysis *in vitro*.

Technic of Administration of Arsphenamin in Relation to Hemolysis.—It is apparent that the possibility of early toxic reactions due to intravascular hemolysis may be readily influenced by technical factors in the method of administration. For example, if a solution is infused rapidly it is entirely likely that the blood in the vein may be so diluted at the site of injection that little or no protection is afforded the erythrocytes mixing with the solution against hemolysis by the drug or by the excess of alkali and hypotonic solution, if water instead of saline is employed. The injection of a concentrated solution and especially rapid injection would tend to produce similar conditions and greatly increase the degree of hemolysis. It is well known that rapid injection and especially rapid injection of concentrated solutions, increase the percentage of toxic reactions and it may well be that the factor of intravascular hemolysis is involved along with other physical phenomena as agglutination, precipitation of proteins and the like.

When arsphenamin is administered by intravenous injection, the solution should be isotonic by preparation with fresh saline solution; it should be dilute (as 0.1 gm. per 20 c.c.) as recommended by the Hygienic Laboratory; too great excess of alkali should be avoided and the solution should be injected slowly in order to minimize the chances of intravascular hemolysis.

Hemolytic Activity of Neoarsphenamin in Relation to Technic of Administration and Toxic Reactions.—Neoarsphenamin is of much less importance than arsphenamin from the standpoint of toxic reactions to be ascribed to intravascular hemolysis. As manufactured at present, solutions are usually neutral in reaction and the drug itself does not produce hemolysis of *whole blood* although concentrated solutions (20- to 40-per cent.) may be feebly hemolytic for washed erythrocytes; in other words, neoarsphenamin itself is very much less hemolytic than arsphenamin and it is entirely likely that *in vivo* the plasma proteins effectually protect the corpuscles against its hemolytic action as they do in the test tube. *Dilute solutions of neoarsphenamin in water, however, may be hemolytic* because of the hypotonic state of the solution as observed by Miss Yagle and myself.

Hemolysis after the administration of neoarsphenamin is, therefore, almost entirely a matter of technic of administration. When the usual dose of 0.6 to 0.9 gm. is dissolved in 5 to 15 c.c. of distilled water the solution is not hemolytic for whole blood and its administration does not produce hemolysis. When 0.6 to 0.9 gm. are dissolved in 50 c.c. or more of water, the solution is hypotonic and hemolytic; the more water used, the greater the degree of hemolytic activity. When 0.6 to 0.9 gm. are dissolved in 1 c.c. of water the solution may be hemolytic, but is not apt to be for the whole blood *in vivo* if the solution is slowly injected. From the standpoint of administration, therefore, the usual dose of 0.6 to 0.9 gm. neoarsphenamin should be dissolved in 5 to 15 c.c. if distilled water is employed; if 50 c.c. or more fluid is used preference should be given to saline solution.

Hemolytic Activity of Sulpharsphenamin in Relation to Administration and Toxicity.—Since sulpharsphenamin is sometimes administered by intravenous, as well as by subcutaneous and intramuscular injection, the question of its hemolytic properties likewise becomes a matter of interest in relation to toxic reactions. In my experience, solutions of this arsenical in *saline* are practically without hemolytic activity for whole blood. Concentrated solutions prepared by dissolving 0.5 gm. in 5 c.c. of saline solution may prove slightly hemolytic for washed erythrocytes with the production of methemoglobin when the mixtures are allowed to stand for an hour or more at 37°C., but with whole blood these changes do not ordinarily occur owing to the protection afforded by the plasma or serum. *Solutions in water, however, are slightly hemolytic* for both washed erythrocytes and whole blood, due primarily to the effects of hypotonic solutions.

In practice, the administration of 0.4 to 0.6 gm. of sulpharsphenamin in 5 to 15 c.c. of sterile distilled *water* by intravenous injection, probably produces a slight degree of hemolysis of erythrocytes at the point of injection where the solution comes in contact with the cells before dilution with the blood to the point when tonicity results; when this drug, however, is dissolved in *saline solution* hemolysis probably does not occur at all.

Hemolytic Activity of Atoxyl, Tryparsamid and Other Organic Arsenical Compounds.—In my experience solutions of *atoxyl and tryparsamid in saline solution* are not hemolytic for either whole blood or washed erythrocytes. *Solutions in water may be slightly hemolytic* and more so for washed erythrocytes than for whole blood, due to hypotonicity. As previously mentioned, Crabtree found that solutions of "arsenoxid" in saline were non hemolytic for washed sheep corpuscles.

In searching for the cause of the hemolytic activity of arsphenamin, Crabtree[13] examined solutions in saline of the sodium salts of a number of substituted phenyl arsenic acids and two polyarsenids against washed sheep corpuscles with negative results and his study has shown that the hemolytic activity of the arsenical compounds increased in direct proportion to the number of amino-groups introduced, as has been previously mentioned and discussed.

Rôle of Hemolysis in the Production of Toxic Reactions.—It is apparent that with a few simple precautions in technic the hemolytic activity of arsphenamin, neoarsphenamin and other organic arsenical compounds *in vivo* can be largely or entirely prevented. Arsphenamin is most likely to produce hemolysis, but by using a saline solution instead of water, avoiding an excess of sodium hydroxid and injecting slowly, hemolysis can be greatly reduced since the plasma proteins afford a considerable degree of protection to the erythrocytes against hemolysis by alkali and the drug.

It is highly probable, when hemolysis occurs, that most takes place immediately after injection as the infused solution comes in contact with erythrocytes. As the solution becomes diluted with blood in the veins, hemolysis becomes progressively less and unimportant. Furthermore, it appears that the oxidized products of arsphenamin and its substitutes are non-hemolytic and delayed intravascular hemolysis probably does not enter into the production of the late toxic effects of these arsenical compounds.

The symptoms of toxic action which one may ascribe to hemolysis are those which resemble "protein shock," such as fever, sweating and nausea developing within one to three hours after injection. As previously mentioned, it is to be admitted that very small amounts of hemolysis may be sufficient for these effects and that susceptibility of erythrocytes to hemolysis may vary in different individuals and that concentration of the solutions and

rapidity of injection may be sufficient to break up enough cells to yield reactions of this kind and degree.

Intravascular Agglutination by the Organic Arsenical Compounds in Relation to Toxic Reactions.—Of even more interest and importance than intravascular hemolysis in relation to the mechanism of toxic reactions by arsphenamin and its substitutes, is the possibility of intravascular agglutination of erythrocytes by these medicaments. Early investigations by Meissner,[14] v. Marscholkó and Veszprémi[15] and Schindler[16] of cases of fatal arsphenamin poisoning emphasized the importance of multiple emboli and thrombi, especially in the lungs, which were ascribed to the action of arsenic upon the blood-vessels. Lucke and myself[17] regularly noted peculiar "brassy" thrombi of conglutinated erythrocytes in sections of the lungs and other organs of rabbits and rats after intravenous injection of solutions of arsphenamin and to much lesser extent after neoarsphenamin in our series of studies upon the pathological tissue changes produced by these compounds; we ascribed these effects primarily to the fixing fluids employed for the histological examination of the tissues, but I now believe that in some instances agglutination of the corpuscles *in vivo* were responsible rather than conglutination by the fixatives. These and other investigations about to be discussed have indicated that under certain conditions the administration of arsphenamin may cause intravascular agglutination of erythrocytes and produce definite lesions and symptoms of toxic action largely due to such physical factors as thrombosis and embolism.

Agglutination of Erythrocytes by Arsphenamin in Vitro.—In 1920, while Karsner and Hanzlik[18] were investigating the production of "anaphylactoid" phenomena in guinea-pigs by the intravenous injection of agar, acacia, etc., it was found that the injection of therapeutic sized doses of solutions of disodium arsphenamin and neoarsphenamin sometimes produced respiratory distress with pulmonary congestion and hemorrhages but pulmonary distention with emboli and thrombosis were generally absent and the results were ascribed primarily to the effects of arsenic upon the blood-vessels and circulation.

Later Karsner and Hanzlik[19] observed that solutions of arsphenamin and neoarsphenamin agglutinated *washed* human, cat and guinea-pig erythrocytes in the test-tube and the intravenous injections of the former was believed to produce agglutination and thrombosis in the pulmonary vessels.

Oliver and Douglas[20] subsequently confirmed the observations that solutions of disodium arsphenamin agglutinated *washed* human erythrocytes and the corpuscles of the lower animals in the test-tube. These investigators found that the corpuscles first absorb the drug, but that agglutination does not result unless an electrolyte is present which results in producing a physical change in the degree of dispersion of the arsphenamin in solution. They also observed that solutions of arsphenamin exposed to air lose in agglutinating power, which is interesting in view of the findings of Crabtree referred to above, to the effect that oxidized solutions lose in hemolytic activity.

Subsequently Oliver and Yamada[21] found that the agglutination of washed erythrocytes by arsphenamin *in vitro* may be largely prevented by the presence of serum or other hydrophilic colloids which naturally reduce the significance to be placed upon the possibility of agglutination *in vivo* as a cause of toxic reactions. Inhibition of agglutination of washed corpuscles in the test-tube by serum and other colloids was believed to be due to an interference of union of arsphenamin with the corpuscles as well as to interference with the act on of the electrolyte sodium chlorid. Of the colloids studied, namely, gelatin, serum, gum arabic, egg albumin and starch, most protection was afforded by gelatin, serum and gum arabic named in the order of efficiency. In a subsequent study of the mechanism of protection of erythrocytes against the agglutinating activity of arsphenamin by serum and other colloids, Oliver and Douglas[22] found that the plasma proteins, especially the globulins, unite with the arsphenamin and thereby prevent the binding of the drug by the corpuscles. This was believed to be the physiological method of protection against agglutination *in vivo* following the intravenous injection of therapeutic doses. My investigations conducted with the assistance of Miss Richter, have amply confirmed these observations of Oliver and his associates and may be briefly summarized as follows:

(1) For washed human erythrocytes solutions of the *disodium salt of arsphenamin* caused slight but definite agglutination in final dilutions as high as 1:3000 to 1:25000; this means

that 0.0003 to 0.0004 gm. of arsphenamin produced some agglutination when added to 1 c.c. of a 2-per cent. suspension of washed corpuscles.

(2) Different lots of arsphenamin were found to vary to a slight degree in agglutinating activity. All agglutinated in final dilution of 1:3000; an occasional lot produced some microscopic agglutination in final dilutions as high as 1:100,000.

(3) *Acid solutions of arsphenamin* caused greater agglutination of washed erythrocytes than solutions of the monosodium and disodium salts.

(4) As previously stated, Crabtree observed that "oxidized" solutions of disodium arsphenamin were less hemolytic than fresh solutions. Similar results were observed by us and we have also found that the loss in agglutinative properties is even more marked.

(5) Heating and shaking solutions of the disodium salt of arsphenamin has a tendency to reduce agglutinating activity.

(6) No noteworthy differences were found in the agglutination of erythrocytes of different healthy non-syphilitic human beings by the same lot of arsphenamin.

(7) The corpuscles of syphilitic individuals under treatment with arsphenamin and neoarsphenamin occasionally showed a slightly increased susceptibility to agglutination and especially after three or more injections had been given.

(8) Glucose increased the susceptibility of washed human erythrocytes to agglutination by arsphenamin. For example, solutions of disodium arsphenamin in saline agglutinated 1:3000 to 1:6000; solutions of the same arsphenamin in 5-per cent. solutions of glucose in saline agglutinated the same erythrocytes in final dilutions as high as 1:200,000.

The protection afforded corpuscles by hydrophil colloids as serum or plasma, gelatin, acacia, etc., against agglutination by arsphenamin is due, according to Oliver, to a binding of the arsphenamin by the colloid which thereby protects the corpuscles. The amount of arsphenamin bound was found to be markedly influenced by the H-ion concentration of the medium in which the reaction occurred. With serum or plasma it is believed that the globulins are the active protective agents and the degree of protection afforded by these is quite marked. The protection afforded by gelatin is also quite marked; for example, solutions of disodium arsphenamin in saline solution caused some agglutination of washed human corpuscles in final dilutions as low as 1:600. *Acacia* is much less protective of corpuscles against agglutination and hemolysis by disodium arsphenamin. In the same experiments 2-per cent. solutions afforded no protection against hemolysis by 1:400 solutions but $\frac{1}{8}$ per cent. solutions protected against agglutination.

Agglutination of Erythrocytes by Arsphenamin in Vivo in Relation to Toxic Reactions.—Since the plasma proteins so effectually protect erythrocytes against agglutination by arsphenamin *in vitro*, one may naturally conclude that intravascular agglutination is not produced by the amounts ordinarily administered at one time by intravenous injection in the treatment of syphilis. But it is possible that the rapid injection of solutions of arsphenamin and especially of concentrated solutions may so dilute the blood in the vein at the site of injection as to "saturate" the plasma proteins and thereby reduce the protection afforded by the plasma so that the excess of "unbound" arsphenamin may unite with corpuscles and produce some agglutination; certainly this possibility exists when acid solutions are administered by mistake and evidence is at hand to show that part of the severe toxic reactions following this technical error are to be ascribed to intravascular agglutination.

In a study by Lucke and myself[23] of the histo-pathological changes produced in rabbits by the intravenous injection of arsphenamin, emboli were commonly observed in many of the internal organs and especially in the lungs. These were especially conspicuous after the intravenous injection of fatal amounts of acid solutions of arsphenamin and likewise after the injection of large and lethal amounts of solutions of the disodium salt. But even after repeated intravenous injections of rats and rabbits with the disodium salt in dose of 0.010 gm. per kilo of weight which corresponds to 0.6 gm. per 60 kilos or approximately the dose for adult human beings, emboli and thrombi of erythrocytes were sometimes found not only in the lungs but likewise in the brain, liver, spleen and other internal organs. Lucke and I at the time thought that these intravascular masses were composed of precipitates and partially hemolyzed erythrocytes and that in part they were produced after death by the fixing fluids employed. But since then the work of Oliver and

Yamada[24] has shown that in the rabbit solutions of the disodium salt of arsphenamin may produce intravascular agglutination and that the thrombi may be masses of agglutinated cells and especially after the intravenous injection of massive doses.

These investigators examined blood from the vena cava, ear veins and perfusion fluids from the spleen and lungs of rabbits at intervals of a few minutes to six hours after intravenous injections of the drug and observed evidences of agglutination after the injection of doses varying from 0.110 to 0.420 gm. per kilo; especially striking results were observed in those animals succumbing almost immediately. Clumps of agglutinated erythrocytes were found on both sides of the vascular system, in the right side of the heart and in the left ventricle. Evidences of embolism were found in practically all organs either by direct inspection with a hand lens or microscopically after sectioning of the tissues and the symptoms produced as dyspnea, convulsions and death were likewise observed after the injection of corpuscles previously agglutinated in the test tube by arsphenamin and similar to the effects produced by oil embolism.

Essentially similar results were observed in the experiments of Miss Richter and myself employing the methods described by Oliver and Yamada. Rats injected intravenously with solutions of disodium arsphenamin in doses of 0.050 to 0.200 gm. per kilo regularly showed agglutinated masses of erythrocytes in the right auricle and inferior vena cava when examined within a few minutes after injection. Rabbits under chloral anesthesia were injected by way of the ear veins with 2-per cent. solutions of disodium arsphenamin and the blood of the external jugular vein examined at frequent intervals. After the injection of 20 c.c. corresponding to about 0.2 gm. per kilo and at the rate of about 2 c.c. per minute, agglutinated masses of corpuscles were found in the jugular blood eight minutes after injection; masses were also found in the right auricle of the heart, but not in the inferior vena cava. Similar but less marked effects followed the injection of 10 c.c. of solution corresponding to about 0.1 gm. per kilo of weight since the rabbits weighed about 1800 grams.

It is to be carefully borne in mind that these effects were produced by very large doses of disodium arsphenamin; the smallest dose namely, 0.1 gm. per kilo, being at least ten times the maximum amount ordinarily administered to human subjects at one time. With smaller doses as 0.04 to 0.01 gm. per kilo, Oliver and Yamada were unable to definitely determine if any intravascular agglutination occurred since the occasional masses of coalesced corpuscles sometimes found in the tissues by histological methods may have been produced by the fixing fluids as surmised by Lucke and myself in our earlier studies. But it cannot be said that agglutination may not occur after the intravenous injection of alkaline solutions of arsphenamin in therapeutic doses, as 0.6 gm. for an adult. So many physical factors enter into the mechanism as the concentration of plasma proteins and electrolytes, the hydrogen ion concentration of the blood, etc., that it may be possible for intravascular agglutination to occur although severe symptoms and lesions may not be produced. This is particularly true if concentrated solutions are rapidly injected and to a lesser extent by the rapid injection of dilute solutions. When acid solutions are accidentally injected intravenously, the chances of intravascular agglutination is tremendously increased and doubtless plays a part in the symptoms and lesions produced.

Granting that under certain conditions intravascular agglutination may occur after the intravenous injection of arsphenamin in the treatment of syphilis, what symptoms may be expected? If extensive agglutination is produced, as by the injection of acid solutions, the immediate effects of

pulmonary embolism may be expected with dyspnea, cough and pain in the chest followed by the development of areas of pneumonia. Similar but less severe symptoms following the injection of alkaline solutions may be likewise due to embolism of agglutinated cells as well as to the production of precipitates to be described shortly, and whenever broncho-pneumonia follows the administration of arsphenamin effects of these kinds are to be suspected as having occurred.

The effects of pulmonary embolism may also produce in part at least the dilatation of the right side of the heart with a rise in pulmonary blood pressure and a drop in the arterial pressure. Convulsions may be due to emboli in the brain, but the effects of embolism in the liver, spleen, kidneys and other organs are not demonstrable by clinical symptoms.

In other words, the only symptoms of toxic reactions that may be ascribed to intravascular agglutination are those that develop acutely. There is no reason for suspecting that later degenerative lesions and especially in the kidneys and liver are secondary effects; rather these are to be ascribed to the effects of the arsenic and are described in the succeeding chapter. As shown by Ophuls,[25] Warthin[26] and others in studies upon the effects of embolism in general, tissue degeneration results only when capillary obstruction is extreme and complicated by stasis and secondary thrombosis and such degrees of extreme embolism certainly do not occur after the injection of therapeutic doses of arsphenamin in neutral or slightly alkaline solution.

Prevention of Intravascular Agglutination and Other Toxic Reactions by Gelatin.—The question now arises, is it possible to further aid the plasma proteins in protecting the corpuscles against hemolysis and agglutination by arsphenamin by injecting a second protective colloid as gelatin or acacia? Oliver, Yamada and Kolos[27] have studied this possibility quite extensively with special reference to gelatin and have reported that the intravenous administration of disodium arsphenamin in gelatin solutions to rabbits not only affords complete protection against intravascular hemolysis and agglutination, but also affords some protection against the organotropic or chemical toxicity of arsphenamin for such organs as the liver and kidneys. Furthermore, while according to Oliver and his associates saline solutions of disodium arsphenamin may reduce the coagulability of the blood by a destructive effect upon fibrinogen this change does not occur with gelatin solutions; circulatory failure caused by reduction of blood-pressure is also prevented by gelatin by reason of the protection afforded not only against the drug itself, but also against hydroxy ions due to the alkalinity of the solutions which Jackson and Smith believe may be a factor in the circulatory changes.

The results of my experiments have given confirmation to these observations. In the first place the *toxicity of gelatin* itself is very slight. Rabbits and rats have been injected intravenously with amounts as high as 10 grams per kilo of weight without effects insofar as duration of life was concerned. Doubtless the intravenous injection of gelatin may produce some fever, leukocytosis, etc., as do other protein substances but not to the same degree as such protein substances as foreign serum, peptone, etc.

Rabbits injected intravenously with 20 c.c. of 2-per cent. solutions of disodium arsphenamin in saline corresponding approximately to 0.200 gm. of the drug per kilo, regularly show agglutination of corpuscles in the blood of the internal jugular vein, inferior vena cava, right auricle and lungs and incoagulability of the blood. The injection of the same prepared in 0.5- to 2-per cent. solutions of gelatin in saline, autoclaved for 20 minutes, was without these effects.

The maximum tolerated dose of one lot of disodium arsphenamin in saline solution for rats by intravenous injection was 0.240 gm. per kilo; with solutions in 1-per cent. gelatin in saline the dose was 0.280 gm. per kilo. Similar results were observed with other lots of more toxic arsphenamin so that I am able to subscribe to the opinion of Oliver and his colleagues that solutions of disodium arsphenamin in gelatin are slightly less toxic for rats than solutions in saline.

Influence of Gelatin upon the Trypanocidal and Spirocheticidal Activity of Arsphenamin.—Since gelatin reduces the toxicity or organotropism of arsphenamin the very important influence upon therapeutic or parasiticidal activity requires serious consideration and extensive study before an opinion may be expressed upon the practical use of gelatin solutions of arsphenamin in the treatment of syphilis.

Trypanocidal tests were conducted with white rats infected with *Tr. equiperdum* after the methods of Voegtlin and myself described in Chapter X. Solutions of different lots of arsphenamin (disodium salt) were prepared in saline and in 1-per cent. solutions of gelatin in saline previously sterilized by autoclaving for 20 minutes. The results observed with two different arsphenamins were as follows:

Arsphenamin.....	M.T.D.* 48 Hours		M.E.D.† 48 Hours		M.C.D.‡ 14 Days	
	Saline	Gelatin	Saline	Gelatin	Saline	Gelatin
Lot A.....	0.200	0.250	0.006	0.006	0.002	0.003
Lot B.....	0.230	0.250	0.010	0.008	0.002	0.004

* Maximum tolerated dose.
† Minimal effective dose (Voegtlin method).
‡ Minimal curative dose (Kolmer method).

As just stated toxicity for the host is slightly reduced, inasmuch as the maximum tolerated doses are slightly higher when the drug is administered in gelatin solution. However, trypanocidal activity or toxicity for the parasites is also reduced according to the results observed in tests conducted with my method although in duplicate tests according to the Voegtlin method, trypanocidal activity was not materially reduced; however, I am of the opinion that gelatin protects both host and parasites against the toxic action of arsphenamin and that the therapeutic activity of the drug may be slightly reduced when administered intravenously in 1-per cent. gelatin solutions.

Essentially similar results were observed in spirocheticidal tests employing rabbits infected by intratesticular injections of *Spirochaeta pallida* as described in Chapter XXI. The minimal curative dose of arsphenamin dissolved in saline for effecting complete sterilization including the lymph glands was approximately 0.012 gm. per kilo; the dose of the same drugs in 1-per cent. gelatin solution in saline was approximately 0.018 gm. per kilo so that it may be said that solutions of the disodium salt of arsphenamin in gelatin undergo slight reduction in spirocheticidal activity.

Oliver, Douglas and Kolor,[28] however, have found that solutions of disodium arsphenamin in gelatin were retained in animals at a higher concentration for a longer period than solutions in water and that they were as effective in the treatment of experimental trypanosomiasis and rabbits syphilis as the latter, although gelatin arsphenamin was somewhat less trypanocidal *in vitro*.

Agglutination of Erythrocytes by Neoarsphenamin in Vitro.—Neoarsphenamin produces very much less agglutination of washed human erythrocytes *in vitro* than arsphenamin and different lots of neoarsphenamin vary much more in agglutinating activity than the latter; in my experiments about 50 per cent. of lots of neoarsphenamin are totally devoid of this property.

Furthermore agglutination by solutions of neoarsphenamin is very irregular, that is, final dilutions of 1:3000 to 1:12000 may produce slight agglutination after water bath incubation of one hour when 1:200 to 1:2000 dilutions produce no agglutination, indicating the importance of physical factors in the process. Even when agglutination occurs the clumps are much smaller

and fewer in number than produced by arsphenamin. Washed rabbit erythrocytes are more susceptible and slight agglutination may occur in final dilutions as high as 1:100,000 with some lots of neoarsphenamin.

In the presence of serum or gelatin agglutination does not ordinarily occur at all even in final dilutions as low as 1:20. In other words, these colloids afford complete protection of corpuscles *in vitro* against agglutination by neoarsphenamin, as is likewise true of arsphenamin as described above.

Syphilis does not appear to influence the susceptibility of washed human corpuscles to agglutination by neoarsphenamin and repeated injections of the drug to human beings and rabbits have not appeared to influence susceptibility.

Agglutination of Erythrocytes by Neoarsphenamin in Vivo in Relation to Toxic Reactions.—There is no positive evidence of the occurrence of intravascular agglutination of erythrocytes after the intravenous injection of therapeutic sized doses of neoarsphenamin. Lucke and myself[29] found intravascular masses of erythrocytes in the lungs and other internal organs of rabbits and rats injected intravenously with such massive doses of neoarsphenamin as 0.2 gm. per kilo and likewise to a lesser extent after the repeated injection of therapeutic size doses as 0.02–0.03 gm. per kilo, but in some instances at least these may have been caused by the fixing fluids employed.

The intravenous injection of rabbits (ear vein) with 10 c.c. of 4-per cent. solutions at the rate of 1 to 2 c.c. per minute and corresponding to about 0.2 gm. per kilo did not produce any evidence of agglutination in blood drawn from the internal jugular vein or in the blood of the right and left auricles of the heart and inferior vena cava as observed after the intravenous injection of 0.1 gm. of disodium arsphenamin per kilo. Even the injection of 20 c.c. of a 4-per cent. solution corresponding to approximately 0.4 gm. per kilo, since the rabbits weighed about 1800 grams, was without any evidences of intravascular agglutination in tests made of blood from the parts mentioned above at intervals of one to ten minutes after the injection had been given.

It would appear, therefore, that little or no part of the toxic reactions following the intravenous injection of *clear* solutions of neoarsphenamin are to be ascribed to intravascular hemolysis and agglutination. Sometimes the solutions are cloudy and slightly acid in reaction and these may cause a greater degree of physical reactions of this sort but at the present time such compounds are only rarely encountered. With acceptable lots of neoarsphenamin it is apparent that the plasma proteins are able to protect the corpuscles against the feeble agglutinating activity of the drug even when the latter is administered in concentrated solution by intravenous injection.

Agglutination of Erythrocytes by Sulpharsphenamin and Tryparsamid. Since sulpharsphenamin and tryparsamid are frequently administered by intravenous injection in the treatment of syphilis, the question of their influence upon human erythrocytes becomes one of importance in relation to the toxic effects sometimes observed.

Sulpharsphenamin is not nearly as agglutinative for *washed* human corpuscles as arsphenamin. Solutions in water or saline in amounts of 1 c.c. of 1:50 to 1:200 usually produce slight agglutination when added to 1 c.c. of a 1-per cent. suspension of corpuscles (final dilutions 1:100 to 1:400), but not usually in higher dilutions. Different lots and brands of sulpharsphenamin vary somewhat in this property but in the presence of serum agglutination does not occur at all even in final dilutions as low as 1:10.

The intravenous injection of rabbits and rats with doses as large as 0.2 gm. per kilo have shown no evidences of intravascular agglutination in blood

removed from the jugular vein, both sides of the heart and inferior vena cava, as is usually found after the injection of 0.1 to 0.2 gm. of disodium arsphenamin per kilo of weight. In the amounts ordinarily administered to human beings, there is no reason for suspecting that intravascular agglutination occurs or if so, to an extent sufficient for the production of symptoms unless doses of 0.4 to 0.6 gm. are dissolved in 1 to 3 c.c. of water and rapidly injected under which circumstances it is conceivable that so much of the drug may be thrown into the blood at once as may "saturate" the plasma proteins and leave an excess for union with corpuscles with the production of slight agglutination in the vein at the site of injection and especially if the injection is being given in a small vein.

Solutions of tryparsamid are apparently without effect upon washed human corpuscles, solutions as concentrated as 1:5 in saline in amounts of 1 c.c. added to 1 c.c. of 2-per cent. suspension of washed cells have not produced agglutination; at least not the brand of tryparsamid which was available for my experiments.

Intravascular Coagulation of Proteins by the Organic Arsenical Compounds in Relation to Toxic Reactions.—In addition to the possibility of intravascular hemolysis and agglutination as causes of toxic reactions following the intravenous injection of the organic arsenical compounds and especially arsphenamin, the possibility of reactions due to intravascular coagulation of the plasma proteins requires consideration in relation to the mechanism of toxic reactions by arsphenamin and its substitutes. Indeed, this subject received the earliest attention of Ehrlich and others in 1910–1911 in seeking an explanation for the unfortunate fatalities following the intravenous injection of acid solutions of arsphenamin and subsequent investigations have proven that the extremely high toxicity of concentrated acid solutions is due primarily to intravascular coagulation of the plasma proteins and probably to a lesser extent to the precipitation of the drug by the inorganic salts of the blood.

Coagulation of Blood Proteins by Acid Solutions of Arsphenamin in Relation to Toxic Reactions.—Unquestionably the intravenous injection of acid solutions of arsphenamin may, under certain conditions, produce severe and even fatal toxic reactions. Hering[30] who first called attention to this danger and showed that in rabbits the lethal dose of 1-per cent. solutions is 0.004 to 0.005 gms. per kilo and from 0.010 to 0.020 gms. per kilo for dogs, expressed the opinion that the death reported by Fraerikel and Grouves[31] following the intravenous injection of 0.4 gm. of salvarsan dissolved in 15 c.c. of water was due to the effects of the acid solution instead of to hypersensitiveness to arsenic and since then numerous other fatalities have been caused by the injection of concentrated acid solutions.

Soon after the discovery of salvarsan it was found by Michaelis,[32] Miessner,[33] Schottmuller,[34] Fleig[35] and others that acid solutions produced profound changes of precipitation and coagulation when added to blood. In the United States the early investigations of Auer[36] and Joseph[37] also drew attention to this fact and the high toxicity of acid solutions when injected intravenously.

As first shown by Auer and confirmed by Joseph, Fleig and others, the degree of toxicity of acid solutions of arsphenamin for rabbits by intravenous injection varies according to their concentration. Auer found that the injection of 0.5 per cent. solutions were very toxic whereas when 0.1 per cent. solutions were injected the toxicity was reduced four or five times and Fleig observed that 1:50 solutions were about 20 times more toxic than 1:600 solutions.

In other words, the intraveous injection of dilute acid solutions of arsphenamin are much less likely to produce intravascular coagulation and precipitation than highly diluted solutions and this fact has saved the lives of not a few human beings accidentally injected with solutions of arsphenamin in water without neutralization. Joseph has observed that in the test-tube dilute solutions are less likely to coagulate blood than concentrated solutions and Shamberg, Raiziss, Weiss and myself[38] found that acid solutions of arsphenamin in a concentration of 0.25-per cent. or greater will cause coagulation and precipitation in the presence of human serum in the test-tube.

According to Fleig, the phenomenon is one of coagulation of the protein constituents and is ascribed to the action of the phenol group of the arsphenamin molecule. The hydro-

gen-ion concentration of such solutions is approximately 4.7. In addition to coagulation of the plasma proteins there occurs agglutination and hemolysis of the corpuscles as described in preceding sections of this chapter, and likewise a precipitation of the drug itself, to which reference will be later made. In my experiments with Mr. Brown, it was found that the addition of acid solutions to serum *in vitro* results in coagulation of the proteins as well as in a lesser degree to the precipitation of arsphenamin as an insoluble compound by inorganic constituents as described by Danyzs.[39] For example, in one experiment the addition of 20 c.c. of a 2-per cent. solution of arsphenamin in 0.6 per cent. saline to 20 c.c. of serum, followed by removal of the precipitate by centrifuging and analysis of the supernatant serum, showed the following results:

	Serum Albumins Per Cent.	Serum Globulins Per Cent.	Calcium Per Cent.	Phosphorus Per Cent.
Whole serum	3.56	2.38	10.5	3.2
Serum after treatment with acid solution of arsphenamin	2.31	1.65	10.9	2.8

The symptoms, produced by the intravenous injection of acid solutions of arsphenamin the lower animals and man, develop almost immediately and are chiefly respiratory as dyspnea, compression pain of the thorax, cyanosis, cough and collapse; in cases escaping an immediately fatal issue bronch-pneumonia has usually developed.

These symptoms suggest pulmonary embolism and necropsy examinations have shown that this is the case. Meissner first observed these changes in cattle injected with fatal doses of acid solutions and Joseph who first studied the lesions with particular care, observed that in rabbits and dogs precipitates were to be usually found in the blood of the right heart and lungs but not in the arterial blood (left heart). In other words, the intravenous injection of concentrated acid solutions of arsphenamin usually produce immediate physical changes of agglutination and hemolysis of corpuscles and coagulation of proteins as well as precipitation of the drug, the whole forming embolic masses which tend to be filtered out in the capillaries of the lungs followed by the development of acute pulmonary embolism, infarction and edema with the later development of broncho-pneumonia if the acute crisis is not fatal. Lucke and myself[40] found the most extensive intravascular precipitates in rabbits and rats injected with fatal doses of acid solutions and while these were largest and most prominent in the lungs, yet similar but smaller masses were found in other organs indicating the possibility of their passage through the lungs into the arterial blood or the passage at least of the drug itself with subsequent precipitation by the inorganic salt of the plasma. However, the injection of acid solutions are not necessarily fatal and may not necessarily produce symptoms since the questions of concentration and rapidity of injection are of great importance in this connection.

Coagulation of Blood Proteins by Alkaline Solutions of Arsphenamin in Relation to Toxic Reactions.—As stated in preceding sections of this chapter, solutions of arsphenamin neutralized to the point of clearing with sodium hydroxid (monosodium salt) and alkaline solutions containing about one-third excess of alkali (disodium salt) may produce some intravascular agglutination and hemolysis if the dose, concentration and rapidity of injection are sufficient for overcoming the protection afforded by the plasma proteins. But the question now arises, are such solutions capable of coagulating or precipitating the proteins of the plasma *in vivo* and in the test-tube?

Joseph, in the experiments referred to above, saw no evidences of intravascular precipitation or coagulation when dogs and rabbits were injected with large doses of arsphenamin in 1:200 and 1:500 alkaline solutions and concluded that arsphenamin as ordinarily administered by intravenous injection in neutral or alkaline solution does not produce intravascular coagulation as occurs so readily when acid solutions of similar concentration are injected. Fleig likewise found in his experiments upon the toxicity of salvarsan that solutions of the monosodium and disodium salts produced no gross changes when added to blood *in vitro* as were produced by acid solutions. Berman,[41] however, stated a few years ago that alkaline solutions of arsphenamin may coagulate the proteins of the serum of some cases of syphilis showing an increased protein content of the blood and developing immediate reactions of flushing, dyspnea, precordial pain and cough ("nitritoid crisis") after intravenous injections.

As stated in Chapter XLIII, it is true that in some cases of syphilis there occurs an increase of the serum globulins as first described by Rowe[42] employing the refractometric method of Robertson.[43] Earlier studies by Winternitz[44] and Elias, Neubauer, Porges and

Salomon[45] had shown this increase of globulin in syphilis and in my laboratory the investigations of Tokuda[46] amply confirmed the observations of Rowe. But even though in syphilis there may be this increase of serum globulins, does the intravenous injection of alkaline solutions of arsphenamin cause any coagulation? Schamberg, Raiziss, Weiss and myself[47] found that, when solutions of the monosodium salt of arsphenamin were added to serum *in vitro*, that a slight precipiation occurs with the first few drops, but that this precipitate disappears with the addition of alkali and that solutions of the disodium salt produced no precipitation at all. In a later study by Schamberg, Tokuda and myself,[48] further evidence was obtained on the importance of the amount of alkali present in the solution of arsphenamin upon precipitation *in vitro*. Practically always solutions neutralized according to Ehrlich's method to the point of clearing (monosodium salt) produced some precipitation when added to serum *in vitro*, but the addition of a trace more of sodium hydroxid dissolved the precipitate and for this reason we believed that the precipitate was of the drug rather than a coagulation of proteins. In our investigation the serums of individuals yielding no toxic reactions after intravenous injections of arsphenamin produced just as much precipitation in the test-tube as the serums of those that showed toxic reactions after injections of arsphenamin or neoarsphenamin.

It would appear, therefore, that the intravenous injection of neutralized or alkaline solutions of arsphenamin do not coagulate the proteins of the blood; it is possible that the injection of the monosodium salt in concentrated solution may have this effect, but this is not at all likely when the disodium salt is injected even in concentrated solutions. Under these circumstances agglutination may occur and possibly precipitation of the arsphenamin base about to be discussed, but not a coagulation of the globulins or other protein constituents of the plasma.

Coagulation of Blood Proteins by Neoarsphenamin and Other Organic Arsenical Compounds. Solutions of *neoarsphenamin*, *sulpharsphenamin* and *tryparsamid* do not coagulate proteins when added to serum in test tubes even when equal parts of concentrations as high as 10-per cent. isotonic solutions and serum are mixed. In former years, some lots of neoarsphenamin, dissolving with difficulty and yielding cloudy solutions, produced slight precipitation, presumably of the drug, which dissolved immediately upon the addition of a trace of sodium hydroxid, but as manufactured at present, neoarsphenamin produces no visible changes in serum *in vitro* and there are no reasons at all for assuming that coagulation of proteins occurs *in vivo* when this drug is injected intravenously even in concentrated solutions.

Intravascular Precipitation of the Organic Arsenical Compounds in Relation to Toxic Reactions.—In addition to the possibility of intravascular hemolysis, agglutination and coagulation of plasma proteins by solutions of arsphenamin injected intravenously as causes of toxic reactions, the possibility of the formation of precipitates of the drug requires consideration in relation to the mechanism of untoward effects by physical agencies. Danyzs[49] has been especially interested in this subject and has offered an explanation of toxic reactions based upon the hypothesis of intravascular precipitation of arsphenamin and neoarsphenamin worthy of consideration.

Intravascular Precipitation of Arsphenamin.—Danyzs believes that after the intravenous injection of alkaline solutions of arsphenamin that precipitates of the insoluble base may be produced. He states: "A short time after the injection of a disodium solution of arsenobenzol (arsphenamin) this compound loses the sodium which combines with the free carbonic acid forming sodium bicarbonate, leaving the arsenobenzol as an insoluble base. At the same time part of the arsenobenzol which remains as a mono- or disodium salt combines with the calcium phosphates, also producing an insoluble compound. The presence in the blood of free oxygen and sodium chlorid hastens these transformations, while the organic bases contained in the plasma form with the insoluble deposit new soluble compounds."

In other words, Daysz advances the hypothesis that carbon dioxid and the sodium bicarbonate of the blood change arsphenamin into an insoluble base which is carried in the circulation until dissolved by the leucocytes and organic bases of the plasma. The biphosphates of calcium, sodium and magnesium, as well as the chlorids and iron salts of the blood, are alleged to behave similarly. Danysz regards the immediate effects of arsphenamin injections ("réactions du premier degrée") as due not to the toxicity of the drug, but to emboli caused by precipitates resulting from the presence of an excess of certain inorganic ingredients in the blood.

Danysz concludes that the same product can be more or less toxic according as it precipitates more or less rapidly from its solution.

That calcium biphosphate in certain concentrations will precipitate solutions of monosodium arsphenamin in the test-tube, or that unstable or turbid solutions will produce embolism, is easily demonstrable. But to conclude from this experiment that an increase in the calcium biphosphate and other electrolytes in the blood is the cause of the immediate reactions, is a supplementary assertion, which is not, in my opinion, borne out by the facts. Indeed, Jackson and Smith[50] injected intravenously into dogs large doses of various calcium salts and phosphates followed by arsphenamin without in any way increasing the toxicity of the latter. Of interest in this connection is the recent work of Lyman,[51] showing that the calcium content of human blood is quite constant even in pathologic conditions. Jackson and Smith have also studied the effect of an increased carbon dioxid content of the plasma on the toxicity of arsphenamin. They have permitted dogs to rebreathe the expired carbon-dioxid and have observed no influence on the toxicity of the arsphenamin injected, as along as sufficient oxygen was given. The work of Frothingham[52] has, moreover, established the fact that there is no increase in the plasma of bicarbonates in syphilis (and hence no acidosis). An important point not to be overlooked is that the rabbit is unsuitable for the study of this problem, being a herbivorous animal and having a metabolism which is different in many respects from the carnivorous.

From these considerations it is difficult to see, as Rieger[53] has also indicated, how the carbon-dioxid of the blood can abstract sodium from alkaline arsphenamin when it is injected intravenously, even though it may do so in the test tube.

With the assistance of Mr. Joseph L. Gavron, Schamberg, Raiziss, Weiss and I[54] have studied this interesting hypothesis of Danysz with a series of solutions containing the various inorganic and organic constituents in the same proportions as they occur normally in the blood as well as with concentrations of twice that in which they occur in the blood and while it is illogical to infer what may take place *in vivo* on the basis of test-tube experiments, this much is evident: The hypothesis of Danysz is not supported by adequate laboratory experiments either *in vitro* or *in vivo*. We were rather inclined to believe that when arsphenamin is properly nautralized, that is, when disodium and not monosodium arsphenamin is injected, precipitation *in vivo* does not take place.

Jeanselme and Pomaret have claimed that the phenol bodies in arsphenamin may precipitate the plasma proteins, the reaction depending upon the relative acidity of the solution of drug and the speed with which it is injected. They state that the blood of persons who have had "nitrotoid crises" after the injection of arsphenamin has always been found exceptionally acid and that, while a "shock" reaction need not be feared when the bood is highly alkaline, it always occurs when the blood is exceptionally acid.

It would appear, however, from the investigations of others and ourselves mentioned above, that, when the disodium salt of arsphenamin is injected intravenously, precipitates of the drug base are not produced and that such are not to be held responsible for embolism and the production of toxic reactions. Possibly with solutions of the monosodium salt such precipitation may occur and especially if concentrated solutions are injected but if pulmonary embolism and broncho-pneumonia develop under these circumstances agglutination of corpuscles is to be suspected as the cause rather than a coagulation of plasma proteins or precipitation of the drug base. With acid solutions precipitation of the drug is, however, much more likely and may probably add to the production of emboli composed of masses of agglutinated corpuscles, coagulated proteins and the insoluble base of the drug.

Intravascular Precipitation of Neoarsphenamin.—While intravenous injections of neoarsphenamin may produce immediate reactions of flushing, edema of the eyelids, lips or tongue, dyspnea, cough, tremendous fall in blood pressure, etc., and especially the injection of cloudy solutions, there is no evidence that this drug is ever precipitated in the blood and that such physical changes may be responsible for reactions of this kind. Even after the severest of these "nitritoid crises" following the injection of cloudy solutions, the patient does not experience any persistent symptoms and broncho-pneumonia does not appear to follow. Danysz, however, believes that precipitation may occur under exceptional circumstances when the amount of phosphates in the blood is much higher than normal. But he offers no experimental support for this assertion and the established facts in physiologic chemistry speak against it; in the experiments of Schamberg, Raiziss, Weiss and myself referred to above, there were no evidences at all of the precipitation of the drug *in vitro* by any of the organic or inorganic salts of the blood.

CHAPTER XLVI

CHEMICAL CAUSES OF TOXIC REACTIONS PRODUCED BY ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

Having considered in the preceding chapter the physico-chemical properties of arsphenamin, neoarsphenamin and other organic arsenical compounds in relation to the production of toxic reactions and more especially the changes in the physical (colloidal?) chemistry of the blood which their

administration may produce, we may now discuss the toxic reactions ascribed to direct chemical injury of body cells by the compounds themselves, by the products of their oxidation or reduction as well as by the arsenical and other impurities which they may contain.

These effects may be designated for purposes of simplifying the subject as "chemical injuries," because they are apparently due to effects upon the protoplasm of the fixed cells of certain organs rather than the result of physical colloidal changes in the blood among which may be mentioned those that we may readily evaluate as intravascular hemolysis, agglutination, precipitation and such physical injuries as thrombosis, embolism and infarction. Other types of physico-chemical injury, however, cannot be thoroughly studied by present methods, but while injuries due to these factors are usually referable to dosage and technic of administration, the chemical injuries may be produced by small doses administered by technically correct and acceptable methods. Furthermore, while the physico-chemical injuries in relation to toxic reactions are observed practically only when the compound is injected intravenously, the chemical injuries may be the result of subcutaneous or intramuscular injections as well and produced by numerous small or single large doses.

Chemistry of Arsphenamin, Neoarsphenamin and Other Organic Arsenical Compounds in Relation to Toxic Reactions.—It is practically certain that after the administration of arsphenamin and its substitutes a portion is eliminated unchanged, while the larger part undergoes oxidation or reduction depending upon the trivalent or pentavalent character of the compound. Chemical injury of body cells by unchanged compounds may occur, although elimination of such is ordinarily so rapid that it is reasonable to assume that most damage is due to the products of oxidation or reduction and probably to the ionic arsenic itself; at least, it is customary to estimate the chemical toxicity of these compounds and the results of analyses, in terms of inorganic arsenic since qualitative and quantitative tests for organic arsenic are inaccurate and unacceptable by present methods. It is not possible to say which intermediate compounds between arsphenamin as it is injected and arsenic as it stored and eliminated are of most importance in the production of arsenical injuries, since we know so little regarding the fate of these organic compounds in the body, but it is almost certain that the products of oxidation of which "arsenoxid" is the best known example, are highly toxic and important in these respects. At all events, I believe we may safely conclude that most if not all of the chemical injuries following the technically proper administration of arsphenamin and neoarsphenamin and their substitutes are due to arsenical compounds and these refer not only to the molecules of these substances as injected but more especially to the new compounds produced in the body by processes of oxidation and reduction, as well as to arsenical impurities which commercial samples of the medicaments may contain.

Chemistry of Arsphenamin.—Arsenic therefore, unquestionably constitutes the factor of most importance in relation to the production of toxic reactions by both arsphenamin and neoarsphenamin, but, since it is practically impossible to prepare these compounds upon a large commercial scale in an absolutely pure state, other substances in the nature of impurities are generally present in varying amounts. Indeed, commercial arsphenamin is never a pure substance, but a mixture of dihydroxydiamino-arsenobenzene dihydrochlorid, its oxidation products, inorganic impurities as sulphites or sulphates and sodium chlorid, methyl alcohol, ether, free hydrochloric acid, etc.

Raiziss and Proskouriakoff[1] have found that the arsenic of commercial samples of arsphenamin prepared by different laboratories varied from 30.87 to 32.26 per cent.; according to its chemical formula with either two molecules of water of crystallization or one molecule of methyl alcohol, the compound should contain 31.6 and 31.85 per cent. of arsenic respectively, and the general average for most lots is about 31.6 per cent. as stated by Ehrlich, although the theoretical arsenic content of absolutely pure arsphenamin is 34.2 per cent. According to Kober,[2] methyl alcohol is the chief impurity reponsible for this reduction in the theoretical arsenic and he states it is present in all arsphenamin made according to the original method, but is absent from the arsphenamin prepared from aqueous instead of methyl alcohol solutions. Accordint to Raiziss and Proskouriakoff, a lower arsenic content may be also due to the presence of moisture, ether or other organic solvents the result of insufficient drying as well as to the presence of such inorganic impurities as calcium or magnesium chlorid or salts of heavy metals. Higher arsenic content, on the other hand, they claim may be due not only to the absence of water or methyl alcohol, but also to the presence of such impurities as polyarsenical compounds, arsenophenols or inorganic arsenical compounds.

Raiziss and Proskouriakoff state that, according to the formula of arsphenamin, it should contain 5.89 per cent. of nitrogen; actual analyses of compounds prepared by different laboratories showed from 5.34 to 6.02 per cent. According to these investigators a reduction in the theoretical nitrogen may be due to moisture, methyl alcohol or other organic solvents; also the presence of nitrogen free impurities as arsenophenol or those containing small amounts of nitrogen as dissymmetric compounds, inorganic arsenicals or other inorganic impurities. Higher nitrogen values, on the other hand, may be due to the presence of tetramino-dihydroxy-arsenobenzene tetrahydrochlorid which contains 9.8 per cent. of nitrogen and which may readily appear as an impurity, since the commercial 3-nitro-4-hydroxyphenol-arsenic acid from which arsphenamin is prepared frequently contains the corresponding 3-5-dinitro compound. Since most lots of arsphenamin have a low rather than increased nitrogen content, it is probable that the tetramino compound is only exceptionally present as an impurity, but, according to Raiziss and Proskouriakoff, quantitative estimations of either arsenic or nitrogen alone does not indicate the purity of arsphenamin as well as quantitative estimations of both permitting the expression of a ratio between the two which, for arsphenamin prepared according to the original method, is 31.6 per cent. arsenic and 5.89 per cent. nitrogen or a ratio of 5.37.

When arsphenamin is precipitated from methyl alcohol solution in the final stages of its preparation, it may contain one molecule of this substance, free or loosely combined, along with one molecule of water of crystallization, instead of two molecules of water. At the present time it has not been definitely established, however, whether the formula should be written with two molecules of water or one of methyl alcohol and one of water. Ehrlich and Bertheim[3] themselves found methyl alcohol in some lots and similar findings have been reported by Kober,[4] Rieger,[5] Raiziss, Gavron and Falkov,[6] Binz, Bauer and Hallstein.[7] Kober found that the amount of methyl alcohol, free or loosely combined, is not large, being about 7 per cent. or about 0.042 gm. in a dose of 0.6 gm. Others deny that methyl alcohol is present; Gaebel[8] and Myers,[9] for example, state that it contains two molecules of water and Fargher and Pyman[10] claim that arsphenamin precipitated by the methyl alcohol-ether method contains no methyl alcohol, free or combined. It is possible to prepare arsphenamin without this impurity, but the importance of the subject in relation to toxic reactions has been over emphasized since it is practically certain that the small amounts of methyl alcohol present in well dried preparations produces no harm.

When methyl alcohol is firmly combined with arsphenamin, the resulting methylated compound is apt to be more toxic and of decreased therapeutic activity as shown by Bertheim[11] and Rieger states that commercial arsphenamin may contain an arseniureted methyl compound which decomposes either in the ampule or in solution, with the liberation of arsenous oxid or a cacodyl-like substance, responsible for the vasoparesis of toxic reactions. As arsphenamin is manufactured at present, however, the possibility of the formation of these methylated compounds may be said to be excluded.

It is apparent, therefore, that the chemistry of arsphenamin is exceedingly complex and that commercial lots may contain varying amounts of arsenical or other impurities which may be toxic, although it is exceedingly difficult to properly evaluate these factors in exact terms. All commercial samples probably contain "arsenoxid" in amounts varying from 0.4 to 5 per cent. and this substance is certainly more toxic than arsphenamin itself although not as much so as Ehrlich originally believed. During its manufacture various arsenical intermediates and particularly tetro-amino-dioxy-arsenobenzene may be present in traces in some methods of preparation and some

investigators have reported the occasional presence of inorganic arsenic. The combined sulphur compounds which have been studied by Myers and Dumez[12] are probably of little importance and occur mostly as sulphites or sulphates. Various new sulphur derivatives of arsphenamin have been described which are said to be more toxic and more therapeutically active, but these have not been employed in the treatment of syphilis.

Chemistry of Neoarsphenamin.—The chemistry of neoarsphenamin is probably even more complicated than that of arsphenamin, but the impurities which it contains are not arsenicals and therefore of much lesser toxicity and importance than the impurities of arsphenamin.

The arsenic content usually varies from 18.04 to 19.7 per cent., but this is probably only two thirds of the theoretical arsenic content of pure compounds, the low arsenic content of commercial compounds being due to the presence of various substances as free sodium formaldehyd sulfoxylat, inorganic salts as sodium sulphate and sodium chlorid and other non-arsenical impurities.

Raiziss and Falkov[13] found, when neoarsphenamin was dried at 80°C. in a stream of purified carbon dioxid, that 3.63 to 4.46 per cent. loss of weight occurred which was ascribed to the presence of alcohol or water of crystallization. Qualitative tests did not ordinarily show the presence of any inorganic arsenic and the ratio of arsenic to nitrogen is similar to that found in arsphenamin but subject to greater variation.

The total sulphur varies from 8.25 to 11.13 per cent. due to the presence of formaldehyd sulphoxylate condensed with the amino-group of arsphenamin, free sodium formaldehyd sulphoxylate and occasionally traces of free sodium sulphate or sulphur firmly linked with either the nuclear carbon or arsenic and oxidizable only after the complete breaking down of the molecule. Elvove[13A] has recently described a method for determining total sulphur in neoarsphenamin and sulpharsphenamin which depends on the oxidation of the sample by means of permanganate and hydrochloric acid.

The amount of combined sulphoxylate is usually greater than necesary for one amino-group and less than the theoretical amount for both amino-groups; hence Raiziss and his colleagues have assumed that neoarsphenamin contains a mixture of both the mono- and di-substituted compounds and that variation in the completeness of substitution in the amino-group accounts for differences in toxicity and therapeutic activity of different lots of neoarsphenamin.

All samples contain sodium chlorid, the quantity varying greater from 3.4 to 18.6 per cent., but the presence of this substance is of more importance from the standpoint of influencing the arsenic analyses than from the standpoint of toxicity.

Chemical Constitution of the Organic Arsenical Compounds in Relation to Toxic Relations.—Since the discovery of Ehrlich and Bertheim of the remarkable trypanocidal and spirocheticidal effects of the arseno group (As-As) when attached to the nuclear carbon atom of the molecule of organic arsenical compounds, numerous attempts have been made to introduce such molecular changes as would increase the toxicity of compounds for parasites (parasitropism) while reducing toxicity for the host (organotropism). Despite a great deal of work along these lines, it has not yet been possible to establish definite relations and laws between atomic groupings and biological effects of these compounds. Sufficient data have accumulated, however, to show that with the organic arsenical compounds at least some relation exists, not only between atomic groupings and toxicity for the lower animals as determined by the duration of life after the injection of varying amounts according to body weight, but in relation to gross and microscopical tissue changes as well in the physiologically important organs as the liver, kidneys and cardiovascular system.

In this connection it may be mentioned, for example, that the amino-groups of some of the organic arsenicals may be of as much importance as the arseno-groups in relation to both toxicity and parasiticidal effects, by influencing the amounts of compound or its arsenic anchored or brought into

chemical union with the protoplasm of both parasites and body cells. Raiziss, and Falkov believe that one or both of the amino-groups of neoarsphenamin may be linked with sodium formaldehyd sulphoxylate and that the completeness of the substitution of these groups with this substance accounts for irregularities in toxicity and therapeutic activity. The pioneer work of Ehrlich and his associates had shown quite clearly that, in the preparation of neoarsphenamin, a condensation product of arsphenamin with sodium formaldehyd sulphoxylate, this substitution takes place in one amino group and partially in the second with a consequent reduction in toxicity for both host and parasite but more especially for the former. Studies by Raiziss, Schamberg and myself[14] of additional new derivatives of arsphenamin in which both amino-groups contained fatty acid substitutes, have shown a considerable reduction in the toxicity for both host and parasites (trypanosomes), indicating that both toxicity and therapeutic activity of the organic arsenical compounds is somewhat dependent upon whether the amino-groups are free or substituted.

Of further interest in connection with the importance of the amino-groups is the work of Crabtree,[15] who studied the hemolytic activities of the sodium salts of a number of substituted phenyl arsonic acids and two polyarsenids with the general result that hemolytic activity was observed to increase in direct proportion to the number of amino-groups introduced. As shown by Christiansen,[16] the conditions under which the nitro-group is reduced in the preparation of arsphenamin also influences the toxicity and in a general way slow reduction of this group increases hemolytic activity. According to Crabtree, the introduction of two nitro-groups into dihydroxy-arsenobenzene does not confer hemolytic activity and studies of this kind have indicated quite clearly that substitution of amino-groups may reduce not only the hemolytic properties of the arseno-compounds but possibly their chemical toxicity for the fixed cells of the body as well.

Probably most interest from the clinical standpoint has been placed in the relation of the chemical constitution of organic arsenicals in relation to their toxic action on the optic nerves. There is a general impression that pentavalent compounds are more likely to produce such effects than trivalent compounds and especially atoxyl, arsacetin and tryparsamid, all of which have an amino or a substituted amino group occupying the para position with reference to the arsenic. Young and Loevenhart[17] have recently sought to determine whether the toxic effects of these and other arsenicals for the optic tracts were to be attributed to the pentavalent arsenic, to the presence of the amino group, or to the para position of the amino group. Cats and rabbits were employed in their experiments and the action of the drugs studied by means of opthalmoscopic examinations. The general result of their study was to show that for both trivalent and pentavalent organic arsenicals, those with an amino group or a substituted amino group in the para position were most likely to produce optic nerve changes in these animals. Organic arsenicals with the amino group or substituted amino group in the ortho or meta position to the arsenic, produced no lesions in the rabbit. Arsacetin was more toxic than atoxyl and arseno-phenylglycin least toxic. This led them to conclude that in the group of compounds studied, valence of the arsenic is not the most important factor in the production of the optic lesions, although the valence of the arsenic in certain instances may modify the intensity of action. But the most important factor in the production of optic lesions was found to be the presence of an amino group in the para position to the arsenic.

As will be discussed shortly the tissue changes produced by arsphenamin, neoarsphenamin and other organic arsenical compounds, are probably due in large part to the arsenic, although, as stated by Foulerton,[18] it is impossible to ignore the probability that the tissue toxicity of these arsenobenzenes

may be influenced to some extent by the benzene constituent. Certainly the pathological tissue effects that are produced by arsphenamin and its substitutes, atoxyl, etc., do not bear a definite relation to the amounts of arsenic injected according to body weight. The arsenic of arsphenamin, for example, has a greater effect upon the liver than an equivalent amount of arsenic in neoarsphenamin and the arsenic of the latter is somewhat more toxic for the rat kidney than equivalent amounts of arsenic of the former. In other words, the pathological tissue changes produced by different organic arsenical compounds are known to show wide variation even though animals are injected with equal doses on the basis of arsenic equivalents per gram of body weight.

As previously discussed in Chapter I the chief fundamental principle of chemotherapy is based upon the assumption that changes in the molecule of an organic compound, by adding new side chains, closing or substituting others, may result in increasing its affinity and destructiveness for parasites while decreasing or leaving unchanged its affinity and toxicity for the body cells of the infected host. Unquestionably such possibilities exist, as have been shown by Ehrlich and his co-workers for the organic arsenical compounds, but as recently pointed out by Voegtlin, Dyer and Leonard[19] affinity and toxicity of the organic arsenicals for parasites and body cells may likewise depend, in part at least, upon the presence of some substance in the protoplasm of the parasite or body cell for which the compound has an affinity. For example, these investigators believe that the arsenic of arsphenamin and other organic arsenical compounds in the form of the arsenious oxide (R. As:O) is a specific poison for the sulphhydryl (SH) groups which may occur in the protoplasm of both parasites and body cells, constituting, as it were, the theoretical chemoreceptors of Ehrlich. As discussed in previous chapters, Voegtlin and Homer W. Smith[20] have recorded experimental data to show that, after administration, the organic arsenical compounds must be converted into the trivalent oxids before parasiticidal effects become apparent; arsphenamin and other arsenobenzol derivatives by a process of oxidation and pentavalent arsenicals by a process of reduction. But just how the chemical constitution of the organic arsenical compounds, as, for example, the opening, closing or substitution of the amino-groups mentioned above, affect conversion of the compound into the trivalent oxids in the body and how in turn the affinity of the arsenic of these oxids for the SH groups of the parasites and body cells is involved, has not been determined, but investigations of this kind constitute an important advance in our knowledge of the pharmacodynamics of these compounds and tends to place the subject of chemotherapeutic research upon a much firmer ground than the theory of chemoreceptors of Ehrlich.

Mechanism of Chemical Union of Arsenic with Body Cells.—I have previously discussed in Chapter I the principles underlying the toxicity or organotropism of drugs for body cells, mentioning the theory of chemoreceptors advanced by Ehrlich to explain the union between compound and cells and more particularly the more or less specific tissue affinity of some compounds for certain organs, as well as the recent work of Voegtlin and his associates mentioned above, showing that arsenic is bound to cells by means of the strong chemical affinity between arsenic and the sulphur compounds in the protoplasm of cells. I wish at this time to describe this important work in more detail, as it represents a logical explanation for the mechanism by which arsenic unites with cells, although it does not explain how toxic effects are produced when once arsenic has entered into combination with the protoplasm.

Voegtlin, Dyer and Johnson have drawn attention to the great reactivity of arsenite for hydrogen sulphid and state that "arsenoxid" also reacts with the greatest ease with this sulphur compound as well as with sulphhydryl (R.SH) compounds. It, therefore, seemed quite logical to them to consider the possibility that arsenic might react with a protoplasmic constituent containing sulphur, especially as Heffter[21] in 1908 had demonstrated the fact that the reducing properties of fresh tissues was due to the presence of a "protein-like" substance containing a sulphhydryl (SH) group. Finally, Hopkins[22] isolated from yeast and mammalian tissues a remarkable autoxidizable substance containing a sulphhydryl group designated as "glutathione" which Hopkins and Dixon[23] demonstrated, by means of experiments on surviving frog's and mammalian muscle, was concerned in the processes of oxidation and reduction in living cells.

Voegtlin and his associates state that *Tr. equiperdum* contains an SH group which probably explains the toxic effects of arsenic upon these parasites. Furthermore, they have shown that compounds containing an SH group, like the reduced form of glutathione, sodium thioglycollate, sodium thiosalicylate and glyclycystein, counteract the toxic action of arsenoxid on these trypanosomes, both *in vitro* and in the circulating blood of infected rats, presumably by a union of the arsenic with these compounds by means of their SH group before the arsenic has united with the SH group of the parasites. In addition, these investigators claim that the administration of glutathione, sodium thioglycollate and the other SH compounds previously mentioned, greatly reduced the toxicity of arsenoxid for the white rat, delaying both the onset of toxic symptoms and the time of death, presumably by uniting with and detoxifying a portion of the arsenic before the latter had united with the body cells. It is of particular interest to note that in their experiments sodium thiosulphate and sulphite were without effect, although the former substance has been advocated for the treatment of arsphenamin jaundice and dermatitis. The coorresponding disulphids (RR.S-SS.R) of the above mentioned SH compounds were much less effective or practically without effect and amino-acids containing no SH group as well as glucose, lecithin, and inorganic salts, were without detoxifying activity.

On the basis of these experiments, Voegtlin and his associates have advanced the theory that arsenic in the form of the trivalent oxids (R.As:O) is a specific poison for the sulphhydryl (SH) group of glutathione and possibly other SH compounds which may occur in the protoplasm of living cells. They have shown that SH compounds injected intravenously are partly oxidized and may protect trypanosomes against the toxic action of arsenic or more importantly, diffuse in part into the tissues and protect the cells against arsenic. Voegtlin, Dyer and Leonard[24] have found that an intravenous injection of reduced glutathione inhibits the toxic action of arsenic in rats. It was also found that the toxicity of arsenic was reduced by feeding rats with a mixture of glutaminic acid and cystine, indirect evidence being obtained on the biochemical synthesis of glutathione from the glutaminic acid and cystine contained in the diet. Cystine however, was found less effective than glutathione as an antidote against arsenic poisoning but the data indicate in the opinion of Voegtlin and his colleagues, that the SH group of glutathione may be regarded as the so-called "arsenic receptor" of mammalian protoplasm.

Whether or not the administration of SH compounds as sodium thioglycollate and sodium thiosalicylate results in counteracting the toxic effects of arsenic when the latter has already united with cells and produced symptoms of arsenical poisoning, is not stated in their report, but the subject is of much practical importance in relation to the treatment of the toxic reactions due to arsenic following the injection of arsphenamin, neoarsphenamin and their substitutes.

Specific Tissue Affinities of the Organic Arsenical Compounds.—If the arsenic of such medical compounds as atoxyl, arsphenamin and its substitutes, etc., enters into chemical combination with the protoplasm of living cells by means of the sulphur (SH) compounds of the latter, how may one explain the greater affinity shown by some arsenical compounds for certain organs? And there can be no doubt that such selective affinities exist among the organic arsenical compounds which appear to bear a relation to chemical constitution, as shown by the gross and microscopical tissue studies of Pearce and Brown with such compounds as arsenious acid, atoxyl, arsacetin, arsenophenylglycin, arsphenamin, neoarsphenamin, etc. Furthermore, as will be later discussed, the arsenic of neoarsphenamin appears to have a greater effect upon the kidneys of the lower animals than equal amounts of arsenic in arsphenamin per kilogram of body weight. Of course, it is to be

expected that such organs as the kidneys and liver may show the maximum degrees of injury by reason of their enunctory functions or, as in the case of the liver, by reason of storage of arsenic in addition, but my remarks are concerned more with the question of why one type of arsenical will produce predominantly vascular injuries of organs while with another the changes are mainly parenchymatous, etc., showing a difference in affinity for different cells in the same organ. It may be that the atomic groupings of the compound determine primarily its affinity for certain organs or cells, although if Voegtlin is correct that the organic arsenicals are oxidized or reduced to trivalent oxids before toxic effects are produced and finally to inert pentavalent compounds, it is difficult to understand the mechanism of the apparent selective affinities of some arsenical compounds for certain organs. Possibly the distribution of sulphhydryl compounds in the cells of different organs may be partly responsible as affecting chemical affinities, but the subject is one requiring further investigation for accurate information.

Mechanism of the Toxic Action of Arsenic.—Before, however, considering the pathological tissue changes and toxic symptoms that may be ascribed to the chemical combination of arsenic with cells following the administration of arsphenamin and its substitutes in the treatment of syphilis, it may be well to briefly discuss prevailing views upon the pharmacodynamics of arsenic, that is, the mechanism of the action of arsenic upon the protoplasm of living cells.

Largely on the basis of the investigations of Binz and Schultz,[24a] it is commonly stated that the toxic effects of arsenic upon cells is due to interference with protoplasmic oxidation. These investigators advanced the theory that arsenious acid is oxidized to arsenic acid in the living cells, and the latter again reduced to arsenious acid, the alternate oxidation and reduction withdrawing and supplying oxygen and in this way exerting injurious effects. If this were true both forms of arsenic should possess the same toxicity, which, as shown by subsequent investigators, is not the case for the higher mammals; as stated by Cushny, "while arsenic acid appears to be reduced and arsenious acid oxidized in the tissues, these processes are probably only gradual. Otherwise it would be difficult to explain how arsenious acid is so much more poisonous than arsenic acid; for if the latter were readily reduced to arsenious acid, it would be equally toxic." Sollmann also raises objection to this oxidation and reduction theory and states that it is not tenable. In other words, we do not yet know how arsenic acts in the living cells and particularly how it produces toxic or abnormal changes. We know considerable concerning the histological changes that may be produced and likewise of the resulting gross lesions and consequent symptoms, but of what goes on after the arsenic has entered into combination with the protoplasm we are yet in ignorance. Possibly the recent work of Voegtlin and his associates just described, showing that arsenic may enter into combination with cells by means of the sulphur compounds in the protoplasm of the latter, may open a new channel for investigation and show that disturbances in the sulphur metabolism, rather than interference with protoplasmic oxidation, is of most importance in this connection.

Toxicity of Arsphenamin and Its Substitutes for the Lower Animals in Relation to Toxicity for Human Beings.—As stated in preceding chapters toxicity tests with the lower animals have only a broad and general relation to the subject of toxic reactions in human beings. The Hygienic Laboratory requires that arsphenamin (disodium salt) shall be borne by rats for at least forty-eight hours in dose of 0.120 gm. per kilo; this is about 12 times more per body weight than ordinarily administered to human beings at one time (0.6

gm. per 60 kilograms or 0.010 gm. per kilo). The requirements for neoarsphenamin are that rats shall bear at least 0.240 gm. per kilo for seven days which is about 16 times more per body weight than ordinarily given a human adult in one dose (0.9 gm. per 60 kilograms or 0.015 gm. per kilo); sulpharsphenamin must be borne in dose of 0.300 gm. per kilo by intravenous injection and sodium arsphenamin in dose of at least 0.180 gm. per kilo.

These requirements would appear to be sufficiently safe; probably little is to be gained by raising them since compounds fulfilling these conditions may still produce toxic reactions in human beings due to a wide variety of factors connected with the patient or method of administration which cannot be checked or evaluated by animal tests. In other words, an animal test which requires that a medicament shall be borne in a dose at least 10 times larger than the amount given at one time to human beings according to body weight, would appear sufficient for determining whether the compound is sufficiently safe and acceptable from the standpoint of what may be termed as "gross toxicity;" it has occurred time and again in my experience that compounds and especially arsphenamin, fulfilling these requirements may still produce toxic reactions in human beings and I doubt if these can be avoided by raising the requirements of the rat toxicity test, although it is plain that an arsphenamin passing at 0.150 gm. per kilo is to be preferred to one just passing at 0.120 per kilo, *provided the therapeutic activity is at least the same for both.* Likewise, a neoarsphenamin passing at 0.400 gm. per kilo is to be preferred to one just passing at 0.240 gm. per kilo, provided there is no loss in spirocheticidal power; I know, however, *that not infrequently brands of neoarsphenamin lauded by their manufacturers on the basis of low toxicity are likewise of reduced therapeutic activity. In other words, technical procedures tending to reduce toxicity of neoarsphenamin and its substitutes for the host may also result in a reduction of toxicity for Spirochæta pallida and Tr. equiperdum, and I repeat as my opinion that manufacturers may do well to direct more effort toward increasing the spirocheticidal activity of their compounds while maintaining the toxicity requirements of the Hygienic Laboratory.*

The toxicity values expressed above were for arsphenamin and its substitutes as these are commercially available; they do not refer to the toxicity of absolutely pure compounds as such are not ordinarily available. The toxicity is due, therefore, to the presence of some impurities as well and it may now be profitable to enquire more closely into the toxicity of some of these substances.

Toxicity of Impurities in Arsphenamin and Neoarsphenamin for the Lower Animals. *Toxicity of Arsenoxid and Other Arsenical Impurities.*—In 1912, Ehrlich and Bertheim[25] stated that "the hydrochloride of di-amino-dihydroxy-arseno-benzene shares with other arsenic compounds the peculiarity that it is easily oxidizable. When it is exposed to the air, it will quickly form amino-hydroxy-phenylarsenoxide; however, the formation of an arsenoxide compound takes place immediately, if the experiment is carried on in the usual salt bottle. This fact, is therefore, of the greatest significance in the practical application of the substance as a curative agent, because the arsenoxid is about 20 times as toxic as the pure hydrochlorid of an arseno-compound."

Since then *arsenoxid* (3-amino-4-hydroxyphenyl-arsenoxid) has been most prominently discussed in the literature as a cause for toxic reactions and probably constitutes an important toxic agent, although it is not as toxic for the lower animals as Ehrlich originally surmised. Arsenoxid may be produced by the oxidation of the arsphenamin powder in the ampule and especially if there is a crack in the glass; or it may be produced during the prepara-

tion of the solution for injection and especially by excessive shaking of the alkalinized solution. Myers[26] states that all commercial samples contain from 0.4 to 5 per cent. arsenoxid. The purer forms of arsphenamin are not freely soluble in cold water as previously stated and require the use of hot water for effecting quick solutions; arsenoxid, however, is not produced in appreciable amounts by dissolving arsphenamin in hot water and shaking arsphenamin in hot or cold water has very little effect, although excessive shaking *after* the addition of sodium hydroxid results in increasing the toxicity presumably in part at least by the formation of arsenoxid. However, these are matters largely concerning the toxicity of these compounds in relation to the technic of administration and the subject is discussed with more detail in Chapter XLVIII.

For the white rat the maximum tolerated dose of 2-per cent. solutions of the hydrochlorid of arsenoxid is from 0.020 to 0.030 gm. per kilo of weight. It is, therefore, about 5 times more toxic than disodium arsphenamin for rats. According to Hata,[27] the maximum tolerated dose for mice by subcutaneous injection is 0.0165 gm. per kilo, for rats by intravenous injection 0.035 gm. per kilo and for rabbits by intravenous injection about 0.015 gm. per kilo. According to Hunt,[28] the intravenous injection of this substance produces characteristic symptoms in the rat and when 10 per cent. of arsphenamin in a sample was replaced by an equal weight of the oxid and injected into rats in doses of from 0.100 to 0.120 gm. per kilogram, the symptoms were characteristic of the oxid, and entirely unlike those caused by any other compounds tested by Hunt, with the exception of the analogous sulphid. The further oxidation of "arsenoxid" results in the production of m-amino-p-hydroxyphenyl arsonic acid, which is much less toxic than arsphenamin.

Regarding the toxicity of other arsenical impurities in arsphenamin and neoarsphenamin for the lower animals we have but little information. Inorganic arsenic is occasionally found in arsphenamin but in such small amounts as to be almost negligible although the arsenites are very toxic, the maximum tolerated dose for the rat being about 0.003 gm. per kilo. Traces of the tetra-amino-compound may likewise be found occasionally in arsphenamin manufactured by some methods, but this impurity is usually absent in present day products.

Toxicity of Methyl Alcohol and Inorganic Impurities.—From the standpoint of toxicity, the importance of methyl alcohol has been over emphasized. In the small amounts that may be present, it cannot be held responsible for toxic reactions and is of chief interest in relation to the chemistry of arsphenamin and especially as an explanation in part for the presence of less than the theoretical amount of arsenic, as discussed above. I have found that white rats can bear without apparent injury intravenous injections of methyl alcohol in doses as high as 1 c.c. of 10-per cent. solutions per kilo, which is much larger than the traces to be found in arsphenamin.

The hydrochloric acid of arsphenamin dissolved in water without neutralization which may amount to about 0.2 per cent. of the free acid in addition to that which is combined with the two amino-groups, unquestionably is a toxic factor of great importance, but more especially in relation to injuries due to changes in the physical colloidal chemistry of the blood as discussed in the preceding chapter; furthermore, since acid solutions of arsphenamin are not injected intravenously except by accident, I shall discuss the subject with more detail in Chapter LI.

Whether or not the sulphites or sulphates and small amounts of sodium chlorid present are capable of producing toxic reactions cannot be stated; for the rat the toxicity of these is so slight symptoms are not produced by the injection of the amounts found in 0.100 to 0.200 gm. of arsphenamin and neoarsphenamin per kilogram of weight, although it is possible that the sodium chlorid may produce fever and other slight symptoms in human beings.

Toxicity of Impurities in Arsphenamin and Neoarsphenamin for Human Beings.—It is extremely difficult however, to evaluate the importance of the arsenical and non-arsenical impurities in arsphenamin, neoarsphenamin and their substitutes in relation to the toxic reactions observed in human beings under treatment with these compounds.

Undoubtedly, the products of oxidation which may be present in arsphenamin, neoarsphenamin and their substitutes, as dispensed commercially or which may be produced during the process of preparing the solutions for injection and of which arsenoxid is the best known example, are of most importance; at least, these "oxids" have commanded most attention from the standpoint of toxicity. As stated above, direct toxicity tests with prepared arsenoxid have shown that it is at least 5 times more toxic than disodium arsphenamin and if arsphenamin is improperly dispensed so that oxygen remains in contact with the powder or if the ampule cracks permitting an access of oxygen, it is possible that oxidation will occur with an increase of toxicity. It is commonly stated that oxidation also occurs during the preparation of the solutions and especially if these are excessively shaken; as discussed in Chapter LVIII, the importance of this factor is over emphasized, because arsenoxid production occurs very slowly in solutions of arsphenamin in water (acid solutions) but more quickly in alkalinized solutions; it is not necessary, however, to give the latter more than one or two shakes before filtering and injecting the solution.

It is possible but not probable that traces of intermediate organic arsenical compounds or of inorganic arsenic in arsphenamin, neoarsphenamin and other medicinal organic arsenicals may produce toxic symptoms, but the evidence is not clear and chemical analyses for such have generally yielded negative results.

It is practically certain that the traces of methyl alcohol present in some lots of arsphenamin are of no importance in relation to toxic reactions. The sulphur compounds, and especially those present in neoarsphenamin, may be of more importance in this connection, but animal tests have shown these to be so slightly toxic that they have commanded little or no attention. Other inorganic constituents and especially sodium chlorid may be partly responsible for such mild reactionary symptoms as fever, but the evidence is not clear.

As stated above, the oxidation products, of which arsenoxid is the best known example, have been regarded as most important in relation to toxic reactions. But both Myers and Hunt state that they have not found any commercial preparations of arsphenamin containing sufficient of this substance to account for toxicity. In other words, they believe that toxicity is due primarily to factors other than arsenoxid, inorganic arsenic and intermediate arsenical compounds when arsphenamin is properly prepared and administered. I believe this is true insofar as the immediate toxic reactions are concerned; the late toxic effects as dermatitis, hepatitis with jaundice, nephritis, etc., are, however, to be ascribed to arsenic, but primarily to the arsenic of the compounds themselves rather than to arsenical impurities.

To what then may the early toxic reactions be ascribed? There can be no doubt that some lots of arsphenamin and neoarsphenamin produce such a high incidence of toxic reactions that their administration must be stopped. In 1917, Schamberg, Raiziss and myself advanced the theory that toxic reactions may be due to an impurity in some lots of arsphenamin and neoarsphenamin designated for convenience as "*substance X*." But all attempts to identify this hypothetical substance have failed. Time and again toxicity tests with rats have failed to show an increased toxicity of compounds

that produced a high incidence of toxic reactions in human subjects and chemical analyses for arsenic and arsenical impurities have failed to disclose a possible explanation.

I now believe that the toxicity of these compounds is due to physical factors and that "substance X" is in fact to be ascribed to changes in hydrogen ion concentration of the solutions, viscosity of the solutions and other physical factors modifying the physical colloidal chemistry of solutions of these compounds as administered or subsequently the colloidal chemistry of the blood. It is well known, for example, that cloudy solutions of neoarsphenamin are much more likely to produce reactions than clear solutions and the whole subject has been discussed with more detail in the preceding chapter. It is not uncommonly observed that if several individuals given equal doses of the same arsphenamin or neoarsphenamin that some develop toxic reactions while others do not; under these conditions an impurity should be toxic for all. Such results, however, are not to be ascribed to an impurity but rather to physical factors involving the colloidal chemistry of the solution of medicament or individual changes in the physical chemistry of the blood after injection. Furthermore, toxic reactions by individuals to whom the drugs are given in a technically perfect manner may be due to hypersensitiveness or to pathological tissue changes peculiar for the individual and not to be ascribed to either physical or chemical toxicity on the part of the compound administered.

Insofar as immediate or early toxic reactions are concerned, I believe, therefore, that these are to be ascribed more to physical colloidal factors than to arsenical or other impurities. On the other hand, some immediate and early reactions are due in my opinion to congenital or acquired hypersensitiveness to arsenic and under these circumstances, early reactions may be caused by the arsenic of the compound itself without bringing into consideration arsenical impurities. As stated above, the late toxic reactions as dermatitis, hepatitis, nephritis, etc., are doubtless due in large part to the pathological changes produced by arsenic, but here again these effects may be due to the arsenic of the compounds rather than to arsenical impurities.

Tissue Changes Produced by Arsphenamin, Neoarsphenamin and Organic Arsenical Compounds in Relation to Toxic Reactions.—And now we may with much profit briefly review the subject of the tissue changes that may be produced by the arsenical compounds employed in the treatment of syphilis and other diseases in relation to the production of toxic reactions. The possibility of the production of these changes is not always kept as much in mind in chemotherapeutic research and even in the practical treatment of disease, as their importance warrants. It is true that histological changes may exist at least for a time, without the production of manifest symptoms and more especially, that symptoms may be apparently present for a time without discernible tissue changes, but to judge the toxicity of a new compound for human beings solely on the basis of whether or not clinically toxic reactions and symptoms are produced or on the basis of symptoms and duration of life in the case of the lower animals, is not sufficient and pathological tissue changes may be in some cases the basis for toxic reactions and untoward or dangerous effects.

Of course, most interest is to be placed upon the possible pathological changes that may be produced by those organic arsenicals employed at the present time for the treatment of disease as atoxyl, arsphenamin and neoarsphenamin and their substitutes; likewise most interest is to be placed on the possible injurious effects of these compounds upon the physiologically important organs as the cardiovascular system, brain and meninges, liver,

kidneys and adrenals and especially the effects that may be produced by multiple small therapeutic sized doses rather than single or multiple maximum tolerated doses. The latter are required in a study of experimentally produced lesions in order to intensify the pathological changes, but due care must be exercised against drawing conclusions based exclusively upon such results.

Practical Value of Chemopathological Studies with Compounds of Arsenic.— It may be stated, therefore, that studies of the gross and microscopical tissue changes produced by arsenical compounds are of practical value in several directions, namely: (1) as a means for studying the relationship between chemical constitution and organotropism (toxicity); (2) for determining the special affinity of a compound for certain tissues and organs and (3) in relation to the mechanism of production of toxic reactions and untoward results. All are of special interest to the experimental chemotherapeutist and particularly the first mentioned, while the two latter are of special interest in relation to the practical treatment of syphilis and other diseases. In other words, the physician should always keep carefully in mind that the condition of the patient as well as the disease require consideration and that repeated doses of a medicament as arsphenamin and neoarsphenamin, and more especially mercury, may produce profound tissue changes and in some cases render the treatment more dangerous than the disease. This is not likely to be the case in acute early syphilis with otherwise healthy internal organs, but in chronic syphilis, persistent and long continued efforts to eliminate the infection may result in damaging already diseased and impaired organs. In other words, a good working knowledge of the possible harmful tissue changes that may be produced by the chosen medicament will go far toward a wise selection of doses and spacing of injections, as well as engender a policy of watchful waiting for the earliest evidences of nephritis or other tissue injuries and the employment of rational and efficient means for their prevention and treatment.

Influences of Chemopathological Tissue Changes upon the Course of Syphilis. Aside from the question of the pathological tissue changes that may result from the chemical toxicity of the organic arsenical compounds employed in the treatment of syphilis and other diseases, the question naturally arises, may not the production of such injuries constitute foci of lowered tissue resistance to *Spirochæta pallida* or other parasites and thereby favor dissemination of the infection? This point has been raised in connection with the pathogenesis of neurosyphilis on the basis that too vigorous treatment with arsphenamin or its substitutes may indeed produce vascular injuries and favor infection of these tissues and is not lightly to be dismissed when one recollects in this connection that arsenic is especially apt to produce vascular injuries which may readily enough open up a way for infection of the perivascular spaces if spirochetes happen to be in the blood. It is my opinion that temporary periods of spirochetemia may occur at any time during the course of syphilis, as based upon those instances of successful inoculation of the testicles of rabbits with blood in the different stages, and it may be that in these periods the spirochetes in the blood may find conditions for infection particularly good in tissues primarily injured by arsenic. One may naturally assume that the cells of such areas contain arsenic and that the reverse would be true to the effect that spirochetes finding lodgement would undergo destruction, but we cannot be sure that the arsenic present in such form is spirocheticidal and available data indicates indeed that it is not.

Probably most physicians with experience in the treatment of syphilis have observed in some chronic cases an exacerbation of the lesions and cer-

tain symptoms shortly after the institution of specific treatment well known as the Jarisch-Herxheimer reaction; these reactions, however, are to be ascribed primarily to the stimulation of the spirochetes in pre-existing lesions and, while they may be followed secondarily by a further spread of the disease, one cannot say that either the primary or secondary effects are due to a lowering of resistance by pathological tissue changes endengered by the drug and especially in the case of arsphenamin or neoarsphenamin properly administered in the usual doses.

In other words, it is possible but not at all probable, that arsphenamin and neoarsphenamin may actually favor the dissemination of syphilis or progression of lesions by producing areas of lowered resistance in the nature of pathological tissue changes, but there is no proof of such and clinical experience is against the acceptance of a hypothesis of this kind.

Influence of Pathological States Due to Disease or Produced by Drugs upon the Chemopathology of Arsphenamin and Neoarsphenamin.—However, the converse of this may be true—that is, pathological changes in the kidneys or liver, engendered by syphilis, some other disease or by the previous administration of mercury or bismuth, may influence the production of further tissue changes and consequent toxic reactions by arsphenamin and its substitutes by apparently interferring with the elimination of these arsenicals

Pearce and Brown have stated that it is doubtful whethere there is as yet a single compound of arsenic possessing curative value in experimental trypanosomiasis that produces neither toxic symptoms nor organic tissue changes. I believe that this is true when very large doses are administered, but it is well established that such experimental infections as acute early trypanosomiasis and syphilis may be cured by doses of arsphenamin and neoarsphenamin producing neither toxic symptoms nor tissue changes; I believe the same applies in the treatment of the majority of cases of acute early syphilis of otherwise healthy human beings, but when treatment is complicated by the existence of pathological tissue changes produced by chronic syphilis, some other infection or drugs and especially of the liver, kidneys and cardiovascular system, the question of additional injury due to treatment with arsphenamin or its substitutes becomes a matter of primary importance, and especially if elimination of the compounds through the kidneys and liver is reduced.

Wechselmann[29] has drawn particular attention to the possibility of mercury so injurying the kidneys as to result in the prolonged retention of the oxidation products of arsphenamin and thereby favoring the production of acute toxic reactions and especially a type of acute meningeal congestion with edema designated in Europe as "hemorrhagic encephalitis." In an analysis of fatalities from salvarsan up to 1914, Wechselmann concluded that when these could be ascribed to the drug properly administered, that in almost all there was a history of preceding mercurial treatment, and he accordingly issued a warning for extra caution in the treatment of syphilis with salvarsan following the administration of mercury on the basis that encephalitis was due to insufficiency of the kidneys rather than to hypersensitiveness of the brain and meninges.

One may not agree with all of these statements, but it cannot be denied that any pathological condition interfering with the elimination of the oxidized products of arsphenamin and other arsenicals may be expected to increase the chances for the production of pathological tissue changes and doubtless an organ, as the liver, previously damaged by syphilis, is more susceptible to further damage by arsphenamin since it is well established that arsenic is both eliminated and stored in this organ. In brief, the question of

pathological tissue changes that may be produced by arsphenamin or neoarsphenamin is to be considered quite a different problem in the case of chronic syphilis than in a normal healthy lower animal, since in the former predisposing tissue changes due to the disease or previous mercurial and bismuth medication are apt to be present.

Difficulties and Methods in Determining the Chemopathological Tissue Changes Produced by Arsphenamin and Its Substitutes; Influence of Fasting and Diet.—It is by no means easy, therefore, always to determine accurately in cases succumbing after the administration of arsphenamin or one of its substitutes whether death was due primarily to the drug. Of course, in those unfortunate fatalities following the intravenous injection of concentrated solutions of arsphenamin hydrochlorid (acid solutions) little or no difficulty is encountered in determining the cause of death, but when the drug has been properly administered greater difficulties are encountered in differentiating those tissue changes that may be due to syphilis or some other disease or drug (especially mercury) from those produced by arsphenamin or its substitutes. In the tissues of cases which I have had the opportunity of examining both of these factors required consideration and in none could it be stated with conviction that death was due primarily and solely to the drug excepting in one case to whom a physician had administered 0.6 gm. arsphenamin dissolved in 18 c.c. of water without neutralization in mistake for neoarsphenamin.

As stated by Wechselmann, deaths following subcutaneous injections of arsphenamin can hardly be ascribed to the drug as the patients have usually suffered from the severest syphilitic involvements of the internal organs to whom salvarsan was administered as a last resort. The same may be said of those fatalities following intramuscular injections. Fatalities after intravenous injections of arsphenamin have been more common and a few have occurred following injections of neoarsphenamin, but it may be said that many of these, probably the majority, were due either to errors in the technic of administration and especially of arsphenamin, or to severe syphilitic, malarial or other degenerative lesions. One is impressed upon reviewing necropsy records with the large number of instances in which active tuberculosis, widespread syphilitic aortitis and generalized arteriosclerosis, aneurysms, chronic leptomeningitis (especially in Europe in cases of chronic alcoholism), etc., have been found. Except in those cases dying of acute yellow atrophy of the liver in which arsenical poisoning is always to be first suspected it is indeed difficult to decide what relation arsphenamin or its substitutes bore to the cause of death and especially in those cases of chronic alcoholism, severe syphilitic or other infections and chronic illnesses succumbing during treatment with these compounds.

For these reasons the pathological tissue changes that may be produced by arsphenamin and its substitutes must be studied primarily by administering the compounds to the lower animals and especially the dog, rabbit, guinea-pig and rat in order to obtain precise information in this subject. By arranging the doses according to body weight, one may duplicate conditions pertaining to human beings; but here again it is necessary to bear in mind that the kidneys of healthy lower animals, and especially of the dog and rabbit, may show chronic changes, and the brains of monkeys and some rabbits may show varying degrees of perivascular lymphocytic infiltrations, which may be readily enough ascribed to the effects of the drug under study. In my own work I have found healthy white rats especially serviceable for studying the tissue changes produced by arsphenamin and its substitutes, since the animals may be maintained on a mixed diet and repeatedly injected. In my expe-

rience the tissues of normal healthy adult rats on a mixed diet do not show spontaneous chronic lesions as mentioned above in the kidneys of rabbits and these animals are to be especially recommended for histo-pathological studies in chemotherapeutic investigations. In this connection it is worthy of note that Hooper, Kolls and Wright,[30] reviewing the literature upon the influence of fasting and various diets on the toxicity of various drugs for the lower animals and studying the question with special reference to the toxicity of arsphenamin and neoarsphenamin for white rats, observed that the tissue changes and especially nephritis, were most severe in starved animals and those fed sugar alone preceding the injections; a diet of white bread, rolled oats, and whole milk was observed to greatly increase the resistance of these animals and to exert a marked protective action against the kidney injury.

Special care must be exercised when rabbits are employed for studies of this kind. As pointed out by Ophuls, Hooper and Myers and others a large percentage of rabbits have spontaneous kidney lesions and more or less cirrhosis of the liver with round-cell infiltration as a rule rather than the exception. They have further encountered areas of round-cell infiltration in the heart muscle and brain, areas of bronchopneumonia and arteriosclerosis. It is evident therefore that all histopathologic deductions on rabbits should be made with a full knowledge of the occurrence of the spontaneous lesions. This would especially apply to experiments with the arsenic and mercury or bismuth compounds where the drugs are known to produce kidney or liver damage when administered in toxic doses and I shall have occassion to refer to this subject again in relation to the interpretation of histopathological changes in rabbits.

Varying Pathological Tissue Changes Produced by Different Arsenical Compounds.—It cannot be said that the different organic and inorganic compounds of arsenic produce the same kind of tissue injuries; there is no one "type." Rather, as stated by Wechselmann in reference to the kidney lesions, the effects produced by arsphenamin, atoxyl and arsacetin vary considerably and the studies of Pearce and Brown[31] with arsenious acid, salvarsan, neosalvarsan, galyl, arsacetin, arsenophenylglycin and atoyxl administered to dogs, have amply shown that all arsenical compounds do not produce the same type of renal injury. In general, they observed two broad groups of lesions, the red and the pale kidney, with a variety of subdivisions of each group depending upon modifications in the chemical constitution of the compound, dosage, and length of survival of the animal. Histological studies have shown them[32] that, while some arsenicals produce changes in which vascular injury predominates, others produce an equally dominant tubular injury, each compound producing a lesion-comp ex of the kidney that was relatively characteristic for that compound. Pearce and Brown[33] also observed that in guinea-pigs the tissue changes in the adrenal glands of congestion, hemorrhage, disturbances in the lipoid content, cellular degenerations and necroses, and reduction in the chromaffin content varied in character and severity with these different arsenicals according to their chemical constitution and Brown[34] has described varying lesions in other organs as the heart, lungs and liver as well according to the kind of compound administered.

For details regarding the gross and microscopical changes in the kidneys and adrenals of the lower animals produced by arsenious acid, arsacetin, arsenophenylglycin and atoxyl, I would refer the reader to the papers by Pearce and Brown; since only arsphenamin and its substitutes, tryparsamid and atoxyl, are employed at present in the treatment of syphilis, frambesia, trypanosomiasis, etc., I shall confine my remarks entirely to the tissue changes which these compounds have produced in the lower animals and in the case of arsphenamin, to the tissue changes in fatal dases of poisoning of human beings whose tissues I have had the opporunity of studying histologically. Lucke and I[35] have been particularly interested in the histological

changes produced in rabbits and rats by arsphenamin and neoarsphenamin and since a detailed description of our observations along with photomicrographs of tissue changes are to be found in our papers, I shall review the subject here very briefly.

Pathological Tissue Changes Produced by Arsphenamin.—A clear distinction is usually to be made between the pathological tissue changes produced by the intravenous injection of solutions of arsphenamin hydrochlorid in water (acid solutions) and solutions which have been properly neutralized before injection. When the former are injected intravenously, severe reactions are usually produced immediately in both human subjects and the lower animals which may terminate fatally. If death occurs at once or within a few hours, the chief lesions are widespread and intense hyperemia of the brain and meninges, lungs, liver, kidneys and other organs with extensive thrombosis of agglutinated erythrocytes and plasma precipitates. In some organs small capillary hemorrhages may be found, but degenerative lesions are not produced unless survival is for a day or more, although in rabbits Lucke and I observed early parenchymatous changes in the liver and kidneys of the lower animals as early as five hours after injection of acid solutions of arsphenamin. Under these circumstances immediate death is due, therefore, primarily to acute vascular and intravascular changes of which congestion, thrombosis and embolism (especially of the lungs) are the prominent and sometimes sole lesions; in human subjects succumbing within twenty-four hours after the accidental administration of these acid solutions, advanced degenerative lesions in the liver, kidneys and other organs are to be ascribed more to previous medication or infection since the time is too short under these circumstances for the production of severe arsenical degenerations.

The pathological tissue changes produced by *neutralized and alkalinized solutions of arsphenamin (disodium salt)*, as administered by intravenous injection, vary considerably according to dosage. Insofar as the lower animals are concerned the acute lesions can be produced only by massive doses, as 0.100 gm. per kilo or more; some human beings have succumbed after the injection of 0.010 gm. per kilo, but in these cases a hypersensitiveness to arsenic was probably present which is not encountered among the lower animals. The majority of fatalitites among human subjects due to arsphenamin properly administered have occurred, however, after several doses had been given, death being due to chronic rather than acute poisoning.

A great deal of interest is to be placed upon the tissue changes that may occur in the *brain and meninges*, since in Europe salvarsan fatalities have been frequently ascribed to acute congestion with edema of the meninges variously designated as "encephalitis hemorrhagica," "serous apoplexy," etc. In the United States fatalities have not been ascribed to these lesions, but rather to liver and kidney degenerations and the question has been sometimes raised whether or not the original salvarsan of German manufacture was more prone to produce these lesions than the products manufactured in this country.

As far as I am able to determine, the changes in the meninges and brains of rats receiving 0.100 gm. per kilo and in rabbits receiving 0.080 gm. per kilo were identical with both the original salvarsan as prepared in 1914 and 1915 and the products of more recent manufacture in this country. In animals succumbing within two to five days after these doses Lucke and I found no striking or constant changes and after the injection of 8 to 10 doses of disodium arsphenamin in amounts of 0.010 gm. per kilo which corresponds to 0.6 gm. for about 132 pounds, only inconspicuous changes were found like a slight degree of hyperemia of the meninges with no cellular

infiltrations. It is apparent, therefore, that the vessels of the meninges and to a lesser extent of the brain may show the same vasomotor changes of acute congestion as is found widespread in other organs although these changes are not conspicuous with doses corresponding to those administered human beings. As I shall discuss later, there is considerable evidence to show that hypersensitiveness to arsenic, either natural or acquired, undoubtedly occurs in some human beings and may contribute in no small part to the toxic reactions. As is true of all allergic phenomena vasomotor paralysis with acute hyperemia and serous exudation constitutes the chief lesions and it may be that in those salvarsan fatalities ascribed to "hemorrhagic encephalitis," "serous apoplexy," etc., the effects were due to this allergic hyperemia and exudation in addition to the well-known effects of arsenic in producing vasomotor disturbances with acute hyperemia.

After single large doses, Lucke and I observed no constant or striking changes in the *heart* although after 10 or more small doses the hearts of some rats showed irregularly distributed focal areas of degeneration situated sometimes near the endocardium, sometimes beneath the epicardium or deep in the myocardium, with lymphocytic infiltrations which were of special interest in view of the fact that such changes found in the heart muscle of human cases of syphilis may be regarded as foci of spirochetic infection rather than an effect of the drug.

As would be expected, vascular lesions are particularly prominent in the *lungs* and any intravascular blood changes as agglutination or plasma protein precipitation following intravenous injections are particularly apt to show pulmonary embolism. It is no wonder, therefore, that pulmonary symptoms and lesions occupy a prominent place in the toxic reactions of arsphenamin and even after acute symptoms have subsided, bronchopneumonia may follow. After single large doses, Lucke and I observed that vascular changes were prominent and when examined within two days after injection of arsphenamin, marked congestion and small thrombi of conglutinated erythrocytes were seen associated with scattered areas of edema and extravasation of erythrocytes into the air sacs. After the injection of numerous small doses the capillaries were sometimes tortuous and densely packed with erythrocytes, which occasionally were conglutinated. The walls of the air sacs were somewhat thickened and more cellular, due to proliferating fibrous tissue. The whole picture suggested passive congestion of moderately long standing with diffuse capillary edema; pleural changes did not occur.

The tissue changes produced in the *liver* by arsphenamin are likewise of much interest and practical importance, especially in relation to the occurrence of jaundice. In the experience of Lucke and myself the injection of single large doses have shown extensive and striking changes in all animals, but particularly among the rats; these changes were mainly in the form of extensive areas of coagulation necrosis involving all parts of the lobule, but particularly the central and middle portions. Rats succumbing within two days after the injection have shown changes so extensive as to resemble those commonly found in acute yellow atrophy, entire lobules, excepting the most peripheral portions, being necrotic and sometimes flooded with erythrocytes and infiltrated with mononuclear and fewer polynuclear leukocytes. Among animals surviving a week or longer, the areas of necrosis were not so large. But the injection of ten or more small doses (0.010 gm. per kilo) have shown only in some instances slight periportal fibrosis with small areas of focal necrosis, particularly in the peripheral portions of the lobules, with inconspicuous vascular changes. Probably, of all the tissue changes that may be produced by arsphenamin and its substitutes, most interest has been shown

in the *kidney* lesions as influencing the elimination of the compound and the production of toxic reactions. Pearce and Brown have observed profound changes in dogs and essentially similar changes have been observed by Lucke and myself in the kidneys of rabbits and rats receiving similar single large doses. The vascular changes consisted principally of marked congestion of the vessels of the boundary zone and cortex with occasionally minute interstitial hemorrhages along with cloudy swelling, vacuolization and granularity, involving particularly the convoluted tubules of the inner cortical zone which were sometimes infiltrated with lime salts. *However, numerous small doses have not produced such marked changes* and were more in conformity with the lesions observed in human kidneys. It is well known clinically that lesions of the kidneys are not nearly as likely to develop during arsphenamin therapy as during the administration of mercury and bismuth, and the histological changes found by Lucke and myself after the injection of rats and rabbits with 10 or more doses of 0.010 gm. each per kilo are in conformity with this clinical experience. Vascular changes were sometimes prominent and the tubules have occasionally shown minor changes generally confined to the convoluted tubules of the outer cortical zone and spiral portions of the outer boundary zone but frank necrosis was not encountered and evidences of cellular regeneration were frequently seen.

The effects of arsphenamin upon the *suprarenal glands* are of interest in relation to the possibility of such changes producing disturbances in the adrenalin content of the blood in relation to toxic reactions and especially the immediate reaction or "nitritoid crisis." As previously stated, Pearce and Brown have noted profound changes in glands of guinea pigs and rabbits treated with single large doses (0.100 to 0.150 gm. per kilo) and suggest that therapeutic doses of some arsenicals may produce adrenal stimulation. Lucke and I found that, in practically all rats and rabbits injected intravenously with single doses of this size, great reductions were produced in the lipoid and chromaffin contents but among animals receiving numerous small doses the lipoid and chromaffin substances were apparently unaltered or but slightly decreased.

While arsphenamin produces tissue changes in the *spleen*, these have attracted much less attention being principally due to the possible effects of the drug upon erythrocytes and producing no symptoms. Lucke and I found that in rabbits and rats single large doses frequently produced striking irregular areas of coagulation necroses, but multiple small doses produced much less change, the principle effect being one of passive congestion with slight hemosiderosis and fibrosis, particularly in the animals receiving the maximum number of injections.

Pathological Tissue Changes Produced by Neoarsphenamin.—Neoarsphenamin produces tissue changes in rabbits and rats quite similar to those produced by disodium arsphenamin, but with the exception of the kidney changes, the effects are of lesser severity. Lucke and I have found that the vascular changes are similar, but much less extensive; thrombi of erythrocytes are sometimes found, but since neoarsphenamin does not produce such intravascular changes as agglutination, hemolysis and precipitation, it is likely that these are due primarily to vascular injuries. Cellular degenerations and necroses are likewise to be found in the heart, liver and kidneys, but with the possible exception of the kidneys, are of much lesser severity than produced by arsphenamin. Since the lesions are similar to those described above for disodium arsphenamin, I need not review them here, a detailed description based upon the studies made with rats and rabbits having been made by Lucke and myself.[36]

Most interest is commanded by the histopathological changes produced in the liver and kidneys and the question naturally arises, are the effects produced in these organs by these two compounds of similar kind and equal degree?

As found by Lucke and myself, the pathological changes produced in the livers of rats and rabbits were usually slightly more severe after the injection of arsphenamin than after neoarsphenamin; we did not note any particular differences in effects upon the liver. But Dr. G. C. Lake of the Hygienic Laboratory called my attention to the fact that the kidneys of rats succumbing after intravenous injections of neoarsphenamin prepared by several different laboratories presented a "chocolate" appearance, denoting cloudy swelling and more severe parenchymatous changes than after injections of alkaline solutions of arsphenamin. Hooper, Kolls and Wright also found that neoarsphenamin produced 50 per cent. more injury to the kidneys of rats than arsphenamin, when the effects were evaluated in terms of the amounts of arsenic injected. These investigators also found "arsenoxid" about five times more toxic for rat kidneys than arsphenamin and seven and one-half times more toxic than neoarsphenamin.

Subsequent investigations by Lucke and myself[37] have confirmed these observations, at least to the extent that, when rats were injected intravenously with single large doses of arsphenamin and neoarsphenamin in amounts so arranged that the dose of arsenic per kilogram was approximately the same for both compounds, the arsenic of neoarsphenamin was more toxic for the kidneys than the arsenic of arsphenamin. The arsenic of arsphenamin, however, was more toxic for the liver than the arsenic of neoarsphenamin.

But when arsphenamin and neoarsphenamin were administered to rats in small multiple doses comparable to the amounts ordinarily administered to human adults according to body weight, these special renotoxic and hepatotoxic effects were not so much in evidence. For example, a dose of 0.01 gm. of arsphenamin per kilo carries approximately 0.00031 gm. of arsenic and and 0.02 gm. of neoarsphenamin per kilo about 0.00038 gm. of arsenic; rats receiving 10 to 12 doses of these amounts at intervals of 5 to 7 days did not show in the first place, extensive or very marked histological changes in the liver and kidneys and in the second place, the kind and degree of tissue changes are quite similar for both compounds when these are compared with large numbers of animals kept on exactly the same diet in order to minimize individual variations. In other words, the special hepatoxic effects of arsphenamin and the renotoxic effects of neoarsphenamin are brought out by single large doses of these compounds and probably are due to variations in elimination and storage; with multiple small doses, the toxic effects upon the liver and kidneys are less apparent with both compounds.

The same is true of silver arsphenamin. Kolle[38] states that Fischer has determined that rabbits which had received more than 60 injections of 0.07 gram of silver arsphenamin per kilogram intravenously every second day showed no changes of the organs and Goldstein observed no changes in the nervous system. Schlossberger[39] found in rabbits that received 0.02–0.04 gram silver arsphenamin per kilogram every 3–4 days for 9–12 months, with a total of 3–4 grams, no argyria of the skin. The silver was deposited in the otherwise normal internal organs, especially in the Kupffer cells of the liver as shown by Fischer and to a slight extent also in the kidneys. No functional injury could be demonstrated for the rabbits, which constantly increased in weight.

Hooper and Meyers[40] found that repeated intravenous administration of silver-arsphenamin into rabbits in doses of 10 milligrams or 66.7 milligrams every 3–7 days for a period of 47–70 days did not produce any noteworthy

tissue or blood alterations. In a relative way the amount of silver found on histologic examination of the tissues corresponded with the amount found chemically after incineration. The great individual variation in the amount of silver found at necropsy may have been due to preexisting lesions in the liver and kidneys. In the rabbits that received 10 milligrams silver-arsphenamin per kilogram (3 times the average clinical dose) the silver deposits were inconspicuous.

Pathological Tissue Changes Produced by Arsenoxid, Sulpharsphenamin, Atoxyl and Tryparsamid.—The tissue changes produced by other organic arsenical compounds employed in the treatment of syphilis, trypanosomiasis and other diseases are somewhat similar to those described above for arsphenamin and neoarsphenamin; minor differences are to be noted, but the chief vascular and parenchymatous lesions are similar although varying in severity. For example, *arsenoxid* (para-oxy-meta-amino-phenyl-arsenoxid) produces the same lesions in rats and rabbits as arsphenamin, only more quickly and more intensively. Doubtless, a part of the tissue changes engendered by arsphenamin are due to this oxidation product, although injections of the arsenoxid itself produces greater injury because when arsphenamin is injected a portion is eliminated unchanged before conversion into this trivalent oxid. As previously stated, Hooper and his associates judged that arsenoxid was five times more toxic for rat kidney than neoarsphenamin when compared on an arsenic equivalent basis and seven and one-half times more toxic than arsphenamin (disodium salt). I have observed that *sulpharsphenamin* likewise produces tissue changes similar to those of arsphenamin and neoarsphenamin when injected intravenously in doses corresponding to approximately equal arsenic equivalents; by subcutaneous injection, however, the tissue injuries are less marked although of similar kind.

Pearce and Brown[41] have stated that the subcutaneous or intraperitoneal injection of dogs with *atoxyl*, in dose of 0.020 gm. per kilo, produces parenchymatous and fatty degeneration of the tubular epithelium of the kidneys, with slight congestion and hemorrhage in the boundary zone.

The tissue changes that may be produced by *tryparsamid* (the sodium salt of N-phenylglycine-amide-p-arsonic acid) have been carefully studied by Brown and Pearce,[42] who state that the changes seen in the early stages of the intoxication following large doses in the lower animals consist in moderate vascular dilatation and congestion with a few scattered petechial hemorrhages, occasional effusions into the serous cavities, and widespread cellular degenerations or even necrosis in some organs. The organs mostly involved are the kidneys and adrenals, the cardiovascular system, with an uncertain involvement of the central nervous system, the gastrointestinal tract, the blood, and blood-formative organs; the changes produced in other organs have appeared to be of minor importance. Animals which survived the intoxication rarely showed lesions in organs other than the kidneys and myocardium and doses of the drug slightly below the level of the lethal dose produced only very slight tissue injury. For detailed descriptions of these various organic changes produced by tryparsamid, the reader should consult the publications by Brown and Pearce.

Clinical Significance of the Chemopathological Tissue Changes Produced by Arsphenamin and Its Substitutes; the Toxic Reactions Due to Arsenic.—We may now properly inquire into the clinical and practical significance of these pathological tissue changes which may be engendered by arsphenamin, neoarsphenamin and other organic arsenical compounds in the lower animals in relation to the treatment of syphilis and other diseases of human beings. Upon hasty and superficial examination of the preceding paragraphs concern-

ing these pathological changes, one may readily enough acquire the impression that the drugs are capable and indeed likely, of producing such wide-spread and severe lesions as to preclude their administration in the treatment of disease. But it is to be remembered that the severe lesions were produced especially by very large single doses, amounts almost lethal and ten times or more larger than the amounts given human beings at one time in proportion to body weight, whereas with doses approximately similar to those given in the treatment of syphilis, the tissue changes were much less marked and frequently negligible. In other words, single large doses bring so much of the compound in relation to the body cells, that the tissue affinities and pathological lesions are intensified before elimination and reduction to less harmful substances can occur; with numerous small doses, however, a portion of the compound is quickly eliminated and the cells thereby spared even though the total amount administered in this way over weeks of time may be greater than that given in a single injection.

Chemopathological studies of this kind are of great value in the interests of chemotherapeutic investigations. They have shown, for example, that even though toxic symptoms are not produced or may escape detection, that significant tissue changes may occur. They should form a part of every thorough chemotherapeutic investigation before a new compound is endorsed for administration to human beings and now that an increasing number of drugs are being given by intravenous injection, it is advisable that pathological tissue studies of this kind should be included more generally in pharmacological investigations. But I have already discussed this subject and only mention it here again to lay proper emphasis upon the significance and clinical value of chemopathological investigations.

As previously stated, the pathological changes observed after the administration of arsphenamin, neoarsphenamin, atoxyl, etc., are mostly ascribed to the effects of ionic arsenic, but we do not know from what organic combination this free arsenic is mostly produced. Doubtless the trivalent oxids resulting from oxidation or reduction are an important source, since the injection of arsenoxid is known to be many more times toxic than arsphenamin and neoarsphenamin, but it is entirely likely that the arsenic as stored (presumably in a pentavalent form) is likewise toxic but to a much lesser degree. Doubtless most if not all the tissue injuries produced by the administration of the organic arsenicals are caused by ionic arsenic derived not only from the compounds themselves but also from arsenical impurities in commercial arsphenamin and neoarsphenamin; but concerning these we have much less information.

At any rate, we may safely conclude that most of the tissue changes are due to some form of arsenic, and the outstanding changes are, first an effect upon the capillaries characterized by relaxation and congestion with serous exudation and minute hemorrhages which is a characteristic tissue change of arsenic in general; followed, secondly, by parenchymatous degenerations and necroses. It is entirely likely that the "nitritoid crisis" or immediate toxic reaction of arsphenamin and neoarsphenamin is due primarily to this direct action of arsenic upon capillaries, but in individuals with hypersensitiveness to arsenic, since the effects may be produced by amounts without effect upon the majority of individuals. Likewise, the skin eruptions (urticaria, exfoliative dermatitis, etc.,) may be due to the direct toxicity of arsenic upon capillaries and the excretory glands of the skin, while jaundice is to be ascribed primarily to the necrosis of liver cells by arsenic or to an exacerbation of syphilitic lesions in the liver in the nature of hepatic Herxheimer reactions.

A sharp distinction should be made, however, between the pathological tissue changes produced by single, large, toxic doses of a compound and those that may be produced by multiple, small, clinically non-toxic and therapeutic sized doses; both, and especially the former, are of interest to the pharmacologist and experimental chemotherapeutist, but only the latter are of direct clinical interest in relation to the treatment of disease.

As shown by Lucke and myself, the tissue changes produced in rats and rabbits by ten intravenous injections of arsphenamin in alkaline solution in dose of 0.01 gm. per kilo corresponding to 0.6 gm. for an adult of average weight, are usually inconspicuous and probably without clinically discoverable effects upon the physiological functions of the involved organs; the same is true of neoarsphenamin in dose of 0.02 gm. per kilo, which corresponds to about 1.2 gm. for an average human adult. I believe it may be said, therefore, that the intravenous injection of these compounds every three to seven days in the doses mentioned do not produce tissue changes of sufficient degree and importance materially to influence the physiological functions of the majority of individuals and an enormous number of injections to human beings the world over during the past fifteen years, since these compounds came into wide and general use in the treatment of syphilis, affords clinical confirmation of this assertion. It is true that albuminuria sometimes develops during the treatment of syphilis with these compounds, but not as frequently as heretofore surmized, and indeed, albuminuria due to syphilitic infection or the administration of mercury, is very likely to disappear under arsphenamin and neoarsphenamin treatment.

Probably the toxic effects of arsphenamin and its substitutes upon the kidneys and liver have attracted most attention from the clinical standpoint, and the importance of frequent examinations of the urine for albumin and casts is not to be underestimated; but I believe it may be said with conviction that arsphenamin and neoarsphenamin are not particularly renotoxic and certainly much less so than mercury. As stated above, neoarsphenamin is more apt to injure the kidneys of rats than arsphenamin, but, with the usual small doses employed in the treatment of syphilis, the kidney changes are apparently slight with both compounds and almost neglible under ordinary conditions. For example, the investigations of Rappleye,[43] Elliott and Todd,[44] Bailey and MacKay,[45] Anderson,[46] Weiss and Corson,[47] Raiziss and Brown[48] and others upon disturbances of renal function in human beings or rabbits, as determined by renal functional tests or blood chemical determinations for urea and total non protein nitrogen, creatinine, etc., have shown that multiple, small, therapeutic sized doses of arsphenamin and neoarsphenamin have no injurious effects upon renal function, insofar as these may be ascertained by tests of these kinds. With single, large, toxic doses marked disturbances may occur and I may mention in this connection that Raiziss and Brown found that neoarsphenamin was less likely to disturb the renal function of rabbits than arsphenamin which is not in agreement, therefore, with the results of the histological studies mentioned above, showing that neoarsphenamin was more toxic for the kidneys of rats when administered on the basis of arsenic equivalent per kilo of weight. It cannot be overlooked, however, that both drugs may produce severe types of nephritis in some cases of syphilis and especially if the organs are previously damaged by infection or drugs and particularly by mercury. Probably under these circumstances the more severe effects are due to interference with permeability and elimination with consequent retention of arsenic and other injurious derivatives; in other words, the effects of arsphenamin and its substitutes upon damaged kidneys is apt to be a different matter from effects upon normal kidneys, although in the

presence of syphilitic nephritis improvement rather than further damage is apt to result from judicious medication with these compounds. I believe, however, that in nephritis it is better practice to administer arsphenamin than neoarsphenamin in view of the apparent greater toxicity of the latter for the kidneys.

The same may be said regarding the clinical effects of arsphenamin and neoarsphenamin upon the liver; that is, ordinary, therapeutic-sized doses properly administered do not produce clinically discernible changes in this organ of approximately normal individuals; although in syphilitic or other types of hepatitis, severe effects may be produced. Unfortunately, we do not yet possess tests for liver dysfunction of equal value to the tests for kidney dysfunction in present use, but the liver functional tests so far developed do not show that arsphenamin and neoarsphenamin are particularly hepatotoxic in the usual doses. Greenbaum and Brown[49] for example, found that 75 per cent. of syphilitic patients treated with as many as 45 to 124 intravenous injections of neoarsphenamin showed no evidences of liver dysfunction, as determined by the phenoltetrachlorphthalein test of Rosenthal;[50] it should be stated, however, that this test likewise showed no evidences of liver dysfunction in patients developing acute toxic reactions, although among cases developing jaundice, the test yielded evidences of functional disturbances of the liver which tended to persist even after clinical recovery. Greenbaum and Brown believe, however, that the test may be of value in cases receiving arsphenamin or neoarsphenamin showing signs and symptoms of toxic reactions; Piersol and Bockus[51] have likewise stated that the test as conducted by them possessed diagnostic value for impairment of liver permeability, but Einhorn[52] and Hoxie[53] have not found it sufficiently sensitive and accurate and in all probability it fails to show impairment of permeability in the presence of minor degrees of focal parenchymatous changes as may be produced by small amounts of arsphenamin and its substitutes. Possibly the so-called "hemoclastic crisis" test of Widal, Abrami and Iancovesco[54] and tests for bilirubinemia as described by Bernheim,[55] may yield additional information, but no statement can be made at present of their value in relation to the liver injuries that may be produced by the organic arsenical compounds. At any rate, the treatment of cases of syphilis showing signs and symptoms of hepatitis with arsphenamin and its substitutes involves greater risks and demands extraordinary care; under these circumstances preference is to be given neoarsphenamin, since it is apparently less toxic for the liver than arsphenamin.

The question is frequently asked whether or not arsphenamin and neoarsphenamin produce more or less permanent injuries of the heart and blood-vessels. I believe that, with the usual therapeutic-sized doses, it may be concluded from histological studies among the lower animals that such do not occur. It is possible, as will be shortly discussed, for these drugs to intensify lesions in the cardiovascular system as elsewhere in the way of producing Herxheimer reactions, but I doubt if the drugs alone contribute in any important manner to the production of chronic myocarditis, aortitis, hypertension, etc., of syphilitic individuals undergoing arsenical treatment.

However, it is to be remembered that, among the earliest and most constant tissue effects of the arsenical compounds in general, is an action upon the blood-vessels and especially the capillaries in the form of vasomotor paralysis and endothelial necrosis. Among individuals with congenital or acquired hypersensitiveness to the arsenic of these drugs, immediate vasomotor disturbances are likely to develop after administration in the form of flushing, serous exudation, fall of blood-pressure, etc., constituting the

"nitritoid crisis." While the symptoms and lesions of this acute reaction may be caused by other factors, I believe that in some cases at least, the effects are due primarily to hypersensitiveness to arsenic in which the vasomotor changes are in part due to allergic shock and in part to the direct effects of arsenic upon the blood-vessels. When involving the vessels of the meninges, acute cerebral symptoms may be produced, due to increased cerebrospinal fluid pressure from the serous exudation and minute hemorrhages may result, constituting the so-called "hemorrhagic encephalitis" so prominently mentioned in the German literature as a cause of arsphenamin fatalities. According to the results observed by Lucke and myself in rabbits and rats, ordinary small doses of arsphenamin and neoarsphenamin do not produce prominent changes in the brain and meninges and it is a peculiar fact that in the United States deaths ascribed to arsphenamin and neoarsphenamin have not been regarded as caused by this type of lesion properly designated as acute meningeal congestion with serous exudation and hemorrhage.

The effects produced in the adrenal glands are likewise of interest, although these are inconspicuous in normal animals treated with multiple, small, therapeutic sized doses. But since the acute immediate "nitritoid" reaction bears so many clinical similarities to the lesions and symptoms of acute adrenal insufficiency as originally emphasized by Milian[56] and since the subcutaneous injection of adrenalin affords such prompt relief, one can hardly escape suspecting that the effects of arsphenamin in particular upon the suprarenal glands may be a matter of importance. Hirano[57] has indeed described a deficiency of adrenalin in the blood after injections of arsphenamin, but in the experiments by Lucke, McCouch and myself[58] these finding were not confirmed. The mere fact that the subcutaneous injection of adrenalin prevents or relieves the "nitritoid" reaction is no indication that this toxic reaction is due to adrenal insufficiency; the "nitritoid crisis" is due to acute vasomotor paralysis and this may be caused by the effects of arsenic upon the capillaries and especially if allergic sensitiveness to arsenic exits. In any event, the injection of adrenalin may be expected to afford relief by producing vaso-constriction as it does in allergic reactions and other types of acute vascular congestion. I believe that certain vagotonic individuals may owe their state to adrenal insufficiency and that among these the occurrence of "nitritoid crises" may be unusually high, but I am not at all convinced that the effects produced by ordinary doses of arsphenamin and neoarsphenamin upon the adrenal glands are primarily responsible for these reactions.

So far our discussion has been largely based upon the tissue injuries that may be produced by arsphenamin and its substitutes in approximately normal individuals. But how may these be modified by the presence of syphilis or other infections with resulting pathological changes? In the majority of cases of early primary syphilis, the individuals are otherwise healthy and widespread pathological changes have not been produced by the spirochetes so that the patient may be regarded from this standpoint almost in the light of a normal individual; but in late syphilis the situation may be entirely different. In such we may have organs already damaged and if the liver and kidneys are sufficiently involved to interfere with permeability and elimination, more intense tissue injury may be produced by the injudicious injection of arsenical compounds. Even focal infections ordinarily regarded as of minor importance, may be sufficient for intensifying toxic reactions as so ably discussed by Duke[59] and Stokes,[60] and the influence of previous disease upon the tissue injuries and toxicity in general of arsphenamin and its substitutes becomes a far more important matter than the effects in normal individuals.

It is possible for the medicaments to aggravate syphilitic processes (Jarisch-Herxheimer reactions) and thereby produce lesions and effects not observed in non-syphilitic individuals, and it may be that under these circumstances, further dissemination of the spirochetes is favored by reason of the marked vascular changes of these reactions. It is not difficult to understand that, in organs already the seat of inflammatory changes, the vascular and parenchymatous changes produced by arsenic or other constituents of the organic arsenical compounds may be intensified and especially of the liver, in which arsenic tends to become stored.

In other words, toxic reactions following the administration of arsphenamin and other organic arsenical compounds may be due to faults in the individual patient and some of these may readily enough intensify the pathological tissue changes, but this subject is so broad and important that I will leave further discussion of it for Chapter XLVII. Here, I believe, it may be conservatively stated that amounts of arsphenamin, neoarsphenamin, etc., insufficient for producing pathological tissue changes in normal individuals, may be capable, however, of doing so in diseased individuals and particularly those with advanced chronic lesions of syphilis; for this reason the treatment of cases of chronic syphilis usually presents more and different problems than encountered in the treatment of cases of early syphilis.

CHAPTER XLVII

ABNORMAL CHANGES IN THE PATIENT IN RELATION TO TOXIC REACTIONS FOLLOWING THE ADMINISTRATION OF ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

We may now properly inquire into the relation syphilis itself and other pathological states of individual patients bear toward the etiology of various reactions sometimes following the administration of arsphenamin and its substitutes and especially the more severe and more dangerous reactions. The natural tendency is first to blame the drug and technic of administration, but it need scarcely be mentioned that reactions develop even with the best of compounds administered in an apparently correct manner, and not infrequently the primary cause is to be found in the patient himself.

Fear, Nervousness and Endocrine Disturbances in Relation to Untoward Reactions.—In the first place, plain fear and nervousness are alone sometimes responsible for nausea, vomiting and syncope. I have frequently observed these symptoms during the introduction of the needle and before a single drop of solution of drug has been injected and, curiously enough, men are more likely to show these symptoms than women. As a general rule, this fear and nervousness is dispelled after the first injection or two when the patient is reassured that there is nothing to fear.

But individuals of both sexes with unstable nervous systems, those who blush easily, are readily excited, who develop urticaria on frequent occasions, who present vagotonic symptoms and who have other diseases due in part to instability of the nervous system as hay-fever, vasomotor rhinitis and allergic dust asthmas, are generally more prone, in my experience, to develop minor reactions after intravenous injections of arsphenamin and neoarsphenamin than normal persons. The arsenic of these compounds tends to produce capillary congestion by direct action upon the vessels or upon the vasomotor nerves

and in states of general nervous instability this tendency is apparently increased. It may well be that disturbances of some of the endocrine glands may bear a relation to this subject, but in my opinion these glands are not primarily involved by the drugs; rather there is a pre-existing fundamental change due to other causes which in turn may predispose or intensify the usual or what may be called, the normal or physiological effects of arsphenamin and its substitutes. The acute vasoparetic reaction or "nitritoid crisis" is regarded by some as due to sudden insufficiency of adrenalin in the blood through an effect of the drugs upon the suprarenal glands, but, as discussed in Chapter XLVI, I believe the evidence offered in support of this hypothesis is quite inconclusive and that the reaction is due primarily to an exaggeration of the physiological effects of arsenic upon blood-vessels and especially the capillaries. Even though the administration of adrenalin acts as a specific in the treatment of this particular reaction, it is no argument in itself that the drugs may produce sudden adrenalin insufficiency; adrenalin acts simply as a vasoconstricting agent. Disturbances of the thyroid gland may also act as a predisposing factor and some physicians claim that the generally higher incidence of untoward reactions in women may be due to such as well as to disturbances of ovarian secretions; but our knowledge of the whole subject at present is very indefinite in relation to toxic reactions following the administration of arsphenamin and its substitutes, and at most one can but state that such predisposing factors may exist in some patients.

Focal Infection in Relation to Toxic Reactions.—It is well known that infected gums (pyorrhaea alveolaris) greatly predispose to gingivitis and stomatitis from the administration of mercury and bismuth in the treatment of syphilis; this is due primarily to the fact that both of these drugs are eliminated in part in the mouth and tend to become deposited in these tissues where inflammatory phenomena are excited not so much by local irritation through the excreted or deposited compounds as by reason of these lowering local resistance to microbic infection. Does arsphenamin and its substitutes lower resistance to microbic infection? May some toxic reactions result from exacerbations of microbic infections as the direct or indirect effects of these organic arsenical compounds? Do microbic infections reduce tolerance for the organic arsenical compounds employed in the treatment of syphilis?

In seeking answers to these questions one may first enquire if arsphenamin and neoarsphenamin depress antibody production and the functions of the bone marrow and other antibody producing tissues. In 1918, Toyama and myself[1] showed that small doses of arsphenamin, comparable to those commonly administered in the treatment of syphilis, did not appear to depress antibody-production in rabbits, and similar results have been recorded by Dr. Ainslee Walker of England. But it is likely that numerous large doses of arsphenamin or neoarsphenamin in rare and exceptional cases may produce histological changes in the bone marrow of some human beings, as shown by studies of the leukocytes of the blood reported by Moore and Keidel[2] sometimes amounting to severe aplastic anemias, and thereby reduce resistance to bacterial infection, since the bone marrow is recognized as an important organ of antibody-production, as indicated by the investigations of Hektoen[3] and others. Stokes and Ruedemann[4] have shown that the surgical interference of foci of infection in the tonsils, apices of the teeth and elsewhere during arsphenamin treatment may precipitate severe and even fatal attacks of dermatitis, not so much by the local infection of the skin with bacteria from these foci, as by favoring the production of bacteremia or of allergic sensitization of the skin with the proteins of these organisms.

Moore and Keidel have expressed a similar view in that allergic sensitization to bacterial proteins may occur in cases of focal infection and that the drugs, by reason of the vasodilating properties of the arsenic, bring added amounts of protein to the skin where various dermatoses may be excited. I shall discuss these observations and views with more detail in the succeeding chapter in the section devoted to the etiology, symptoms and treatment of dermatitis and allied reactions, but here I believe one may conservatively state that focal infections, and especially the more severe and advanced grades, are worthy of serious consideration in the treatment of syphilis as a possible predisposing factor to arsenical dermatitis. As shown by Stokes,[5] for example, focal infection may reduce the tolerance of the kidneys for arsphenamin and Duke[6] has shown that focal infection may intensify the lesions of neurosyphilis.

Furthermore, since the liver is recognized as an important depot of storage of arsenic as well as of its elimination, it is not at all unlikely that bacterial infection of this organ and its bile-ducts may be intensified by the arsenic and thereby result in the production of jaundice, not so much the result of direct toxic hepatitis by the drugs as the acceleration of infection of the organ by a lowering of local resistance. The same may be true in cases of intestinal infections, since arsenic is eliminated by the mucosa with the production of vascular changes of hyperemia and exudation.

Arsphenamin and its substitutes may, therefore, in exceptional cases at least, favor the production of dermatitis and jaundice by lowering resistance to bacterial infection or in some other manner stirring them into greater activity, and for this reason the subject of focal or frank infections of individual cases is deserving of due consideration in the preparation of patients for the treatment of syphilis and for added care in our dosage and general treatment.

Syphilis in Relation to Toxic Reactions.—Does the kind and severity of syphilitic lesions bear any relation to the incidence and variety of toxic reactions following the administration of arsphenamin and its substitutes? It is well known that animals infected with virulent trypanosomes, as *Tr. equiperdum*, are much less resistant to the toxic effects of arsphenamin and neoarsphenamin than normal healthy animals. Yakimoff and Yakimoff[7] have found this true of rabbits infected with trypanosomes and I have found it constantly true of infected rats and to a lesser extent with syphilized rabbits. It may be that this increased toxicity of arsphenamin and its substitutes for infected animals is due to a summation of the pathogenic effects of the parasites and the toxic effects of the drugs, but on the other hand, the increased toxicity may be due in part to the liberation of toxic substances by the action of the drug upon the parasites. McIntosh, Fildes and Dearden[8] and others have stated that the fever and rigors so frequently following the administration of arsphenamin to cases of syphilis in the secondary stage are due to liberated "endotoxins" from *Spirochæta pallida* and I believe it may be stated without reserve that mild reactions in all stages of syphilis, but especially in the acute early stages when spirochetic infection is numerically heavy, may be due in part to the liberation of toxic factors from organisms destroyed by the medicament employed and that in a broad and general manner individuals *acutely* infected with *Spirochæta pallida* and, indeed, with other organisms, are more likely to develop untoward reactions than healthy human beings. This is due not only to the possible liberation of toxic substances from parasites, but in large part to a general reduction of resistance to the toxic effects of the drug. Of interest in this connection is the report of Meirowsky and Kretzmer[9] in their excellent monograph in 1914 on the

"Salvarsan Therapy of Syphilis," of the 109 fatalities following the administration of salvarsan up to that time in which it was recorded that 41 per cent. occurred in the secondary period and 27 per cent. in late nerve syphilis. Three-fifths of the fatalities during the secondary stage was attributed to "encephalitis" and it is not unlikely that this was due to the combined vasculotoxic effects of the arsenic and the liberation of toxic substances from spirochetes in the meninges and brain.

Furthermore, it is well known that the administration of mercury or arsphenamin and its substitutes may produce an exacerbation of syphilitic lesions and especially in the secondary stage as originally described by Jarisch, Herxheimer and Kraus; these effects are probably due in part at least to the liberation of toxic substances from destroyed spirochetes and when occurring in the meninges, may produce very dangerous reactions indeed as just referred to above.

There is, therefore, a possible relation between the acute early lesions of syphilis and the occurrence of toxic reactions from arsphenamin and its substitutes. This may not be anything more than a general lowering of resistance from the effects of the infection but in addition, there may be the added effects of liberated toxic substances from destroyed parasites analagous to the very definite lowered resistance of infected rats and rabbits to these compounds. The importance of the influence of acute syphilis upon toxic reactions, however, should not be over-emphasized; indeed, in most instances the incidence of reactions does not appear to be higher than usual in secondary syphilis, except possibly, for a higher incidence of fever and mild chills.

But in chronic syphilis I believe that the lesions may bear a relation to toxic reactions and especially syphilis of the liver in relation to jaundice if the involvement is severe enough to interfere with the functions of this organ in the metabolism and elimination of the compounds. In a strict sense, the stimulation of syphilitic foci in the liver by treatment (hepatic Herxheimer reaction) is not a toxic reaction on the part of the drug; neither is the exacerbation of liver syphilis after the cessation of treatment (hepatorecurrence) and both of these reactions cover the majority of cases of jaundice in relation to syphilis itself, although I cannot dismiss the possibility that syphilitic hepatitis may predispose to jaundice and that in some cases of tertiary syphilis with sub-icteric skins and mucous membranes, the jaundice that appears after several doses of arsphenamin or neoarsphenamin is due to a combined syphilitic and arsenical hepatitis rather than a syphilitic hepatitis alone in the form of a hepatic Herxheimer reaction; Stokes and Ruedemann, however, state that in their series of cases of jaundice, the instrumentality of syphilis was almost negligible.

Likewise in arsenical dermatitis one may surmise that the capillary endothelial injuries produced by *Spirochæta pallida* in the early stages of syphilis may predispose to the deposition of arsenic in the skin with the production of various dermatoses; but such does not appear to be the case. In the series of dermatitis reported by Moore and Keidel only two occurred among 1800 early cases of syphilis (1 in 900 cases).

In chronic syphilis, however, and especially in cases with sufficient involvement of the liver and kidneys to interfere with the metabolism and elimination of arsenic, it is not unreasonable to surmise that the skin may be irritated by excessive amounts of arsenic brought to it for elimination and resulting in the production of vascular lesions as urticaria and fleeting erythemas by intensifying the physiological effects of arsenic upon capillaries in addition to direct irritation. In my experience the majority of the mild

and severe dermatoses associated with the administration of arsphenamin, neoarsphenamin and sulpharsphenamin have occurred among cases of chronic latent and active syphilis and 15 of the cases reported by Moore and Keidel occurred among 7200 late cases of syphilis (1 in 480 patients), although they are of the opinion that the stage of syphilis bears no reaction to the incidence of dermatitis and allied reactions following the administration of arsphenamin.

It is, therefore, extremely difficult to properly evaluate the influence excited by pathological tissue changes produced by *Spirochæta pallida* upon the occurrence of toxic reactions following the administration and especially the intravenous injection, of arsphenamin and its substitutes. One may easily conjecture at great length but with little profit, in view of the very unsatisfactory and incomplete state of our knowledge of the etiology and mechanism of these reactions. I believe, however, that it may be granted in a broad and general manner that chronic syphilitic lesions, and especially of those organs as the liver, kidneys and bone marrow concerned in the metabolism of the organic arsenicals, may exert some predisposing etiological influence at least and that, when such lesions are known to be present or suspected, our choice of remedy and its dosage should be influenced thereby in efforts toward the prophylaxis of toxic reactions.

Toxic Reactions in Non-syphilitic Individuals.—It is well known that the administration of arsphenamin and neoarsphenamin to apparently healthy individuals or individuals with non-syphilitic diseases may produce toxic reactions exactly similar to those observed among syphilitic patients, at least insofar as the milder reactions are concerned. Observations of this kind have established that the milder reactions cannot be ascribed solely to the release of toxic substances from spirochetes by the drugs administered, but that other factors are responsible operative alike in both syphilitic and non-syphilitic individuals.

But may the presence of syphilis act in the reverse manner and actually increase tolerance for arsphenamin and its substitutes in such manner that the incidence of reactions is lower among those with syphilis than among non-syphilitic individuals? Not infrequently one observes that actively syphilitic individuals withstand much larger doses of mercury and iodid than the average normal non-syphilitic individual and I believe the same may be true in relation to arsphenamin and neoarsphenamin. I have the distinct impression that non-syphilitic individuals are more apt to develop milder reactions than those who are actively syphilitic, although I am unable to compare the two groups in relation to the severer reactions as exfoliating dermatitis and jaundice, since I have never given non-syphilitic individuals more than two injections of either drug except in cases of pernicious anemia and in a few other diseases in whom pathology states existed which may have influenced the reactions.

Jarisch-Herxheimer Reaction in Relation to Toxic Reactions.—Of further interest in connection with the subject of syphilis in relation to toxic reactions by arsphenamin and its substitutes and of great practical importance in the diagnosis and treatment of toxic reactions, are the Jarisch-Herxheimer reactions sometimes observed after the first dose or two of these drugs.

In 1895, Jarisch[7] first described a series of cases of secondary syphilis in whom the roseolar eruptions became intensified after 2 to 5 inunctions of mercury and seven years later Herxheimer and Kraus[8] greatly renewed interest in the subject by describing the exacerbation of these lesions by the injection of the first large dose of an insoluble salt of mercury. In 1910 Finger[9] described the exacerbation of the rashes of the secondary stage of

syphilis following the administration of arsphenamin and the reaction is now well known as the "Jarisch-Herxheimer reaction."

These reactions have been observed, therefore, not only after the administration of mercury but also after arsphenamin, neoarsphenamin and bismuth. It is commonly believed that they are not due to the direct toxicity of the drugs, but rather to the effects of endotoxins liberated from destroyed spirochetes. With arsphenamin and its substitutes, however, this may not be the complete mechanism, since it appears that the vasculotoxic effects of arsenic upon the capillaries may play a part in their production. This subject is discussed at further length in Chapters LI and LVIII, but is mentioned here in relation to the influence of syphilis upon the incidence of toxic reactions following the administration of the organic arsenical compounds and especially since similar reactions may occur in organs other than the skin. As just stated, both Jarisch and Herxheimer confined their observations to the influence of mercury upon the acute syphilitic exanthems, but since then and especially since the introduction of salvarsan in the treatment of syphilis, the phrase "Jarisch-Herxheimer reaction" has been applied to the exacerbation of chronic syphilitic lesions in the liver, cardiovascular and central nervous systems, etc., after the institution of specific treatment.

As a general rule, the reactions are not difficult of diagnosis, except when occurring in the liver; the resulting jaundice is frequently difficult of proper classification as discussed at length in Chapter LI, because it may be due to syphilis alone, to an exacerbation of syphilitic hepatis, to the drug alone or to a combination of syphilis and drug. Obviously, however, Jarisch-Herxheimer reactions are of great importance from the standpoint of the treatment of syphilis; apparently they may be prevented by instituting specific treatment mildly rather than intensively, which may be important especially in the treatment of chronic syphilis involving the optic and auditory nerves and similar physiologically important tissues. Their diagnosis is also important because treatment consists in principle of the continuation of the administration of spirocheticidal agents rather than the cessation of treatment as in the case of true toxic reactions.

Syphilitic Recurrences in Relation to Toxic Reactions.—Brief mention may be also made here of the subject of recurrences of spirochetic activity after the cessation of the treatment of syphilis by arsphenamin and its substitutes, since these may be mistaken clinically as delayed toxic reactions. The subject is discussed with more detail in Chapter LVIII.

Sometimes it is noted that, during a course of injections of arsphenamin and neoarsphenamin, no untoward reactions occur or but the mild and usual reactions. A week or two later, however, reactions occur in the form of jaundice, a disturbance of sight, hearing, etc. It is believed that in some instances these reactions are due to a re-activity of syphilitic processes rather than the result of toxic effects of the drug upon the tissues concerned; for this reason they are called "syphilitic recurrences" or "syphilitic recidives" and are sometimes designated according to the organ involved as "hepato-recidive," "meningo-recidive," "optic recidive," etc. Obviously they are of great importance from the standpoint of diagnosis and treatment because in principle they may demand even more rigorous specific medication rather than its interruption as in the case of true toxic reactions.

Non-syphilitic Diseases in Relation to Toxic Reactions by Arsphenamin and Its Substitutes and Contra-indications to Their Administration.—And the question now arises regarding the influence of pathological changes due to non-syphilitic diseases upon the incidence and variety of toxic reactions following the administration of arsphenamin, neoarsphenamin and their

substitutes. Very early in the history of the treatment of syphilis with arsphenamin is to be found the warnings of Ehrlich, Wechselmann and other pioneers against the indiscriminate use of the drug in cases of advanced cardiovascular disease, nephritis, etc.

Pathological changes in the physiologically important organs the result of syphilis, of non-syphilitic infection, drugs as mercury or other causes are important in relation to the toxic effects of the medicinal organic arsenicals in two important ways, namely, (*a*) by the possibility of intensifying the physiological effects of the drugs until they reach an abnormal or pathological degree and (*b*) by interfering with the metabolism of the drugs and the elimination of their end products some of which are apparently toxic and capable of harm if retained too long or are forcibly eliminated by unusual channels.

When these drugs are administered there is almost bound to be a primary increase of blood-pressure before the secondary fall due to the effects of arsenic, by the excitement attending the injection, aided especially in the case of arsphenamin, by the injection of 100 to 300 c.c. of fluid. In advanced cardiovascular disease this sudden rise may be injurious and especially in advanced myocardial involvement, aneurysm, pulmonary tuberculosis with hemoptysis, etc. Furthermore, the vasodilating effects of the arsenic may be dangerous in cases of incipient hemorrhage and the effects of arsphenamin and especially of neoarsphenamin upon lowering the coagulation and bleeding time of the blood may constitute a contra-indication to the use of compounds of this class in hemorrhagic diseases as hemophilia.

Advanced disease of the liver and kidneys likewise call for caution in the administration, not only of arsphenamin and neoarsphenamin but of mercury and bismuth as well, in view of the fact that these organs are so intimately concerned in the elimination of these compounds. It is not to be inferred that the presence of chronic nephritis, or of such symptoms as lead to the suspicion of involvement of the liver and its bile-ducts, constitutes a contra-indication to the use of antisyphilitic drugs; indeed, the very reverse may be true if these lesions are believed to be actually the effects of syphilitic infection. But the presence of lesions of these organs does demand more than the usual care in the selection and administration of remedies in that arsphenamin or neoarsphenamin are to be preferred to mercury and bismuth in the presence of nephritis, because these are less renotropic; while in hepatic disease probably bismuth is to be preferred, because less hepatotropic or arsphenamin in preference to neoarsphenamin, since the former appears to be less hepatotoxic than the latter. And what is more important still, the dosage must be regulated accordingly under the general principle that small frequently repeated doses may be well borne and exert curative effects, whereas large doses may be harmful. This is especially true in the treatment of advanced syphilitic infection of the heart and aorta and is likewise true in the treatment of syphilis of those individuals with syphilitic or non-syphilitic cardiac, renal and hepatic disease.

There are, therefore, very distinct contra-indications to the usual doses of arsphenamin (0.6 gm.) and neoarsphenamin (0.9 gm.) in the form of advanced syphilitic and non-syphilitic diseases as hemophilia, diseases of the endocrine glands such as deficient functioning of the thyroid gland, as stated by Lortat-Jacob,[10] exophthalmic goiter and Addison's disease, advanced cardiovascular disease, severe pulmonary tuberculosis, advanced and acute nephritis, hepatitis and gastro-intestinal catarrh, acute septic infections and constitutional tendency to skin diseases, either because these dangerously intensify the physiological effects of these drugs or dangerously interfere with the elimina-

tion of their products; but in practically all of these conditions smaller doses as 0.2 gm. or less of either may be given with comparative safety, if the presence of syphilitic lesions demands in the interests of the life and welfare of the individual that specific medication shall be given. I repeat as my conviction that the only absolute contra-indication to the administration of arsphenamin and neoarsphenamin from the standpoint of toxic reactions is arsenical hepatitis, provided that small doses are given (0.2 gm. or less), although the list of contra-indications to the usual large doses is by no means small or negligible. The list of contra-indications to single large doses, and especially large first doses, may be extended by including those syphilitic lesions in which sudden exacerbations (Jarisch-Herxheimer reactions) may be dangerous or disastrous; these are fully considered in Chapter LI, but here again it may be stated that even these are avoidable by a conservative attitude on the part of the physician and adherence to the principle of starting with small gradually increasing doses rather than the administration of large doses at the beginning of the treatment of those cases of syphilis in whom these reactions, if they occur, may be dangerous.

Administration of Mercury and the Iodids in Relation to the Production of Toxic Reactions by Arsphenamin and Neoarsphenamin.—Of special interest, however, in relation to the influence of non-syphilitic diseases upon the incidence and severity of toxic reactions from the administration of arsphenamin and its substitutes, is the effect of the previous or simultaneous administration of mercury. Wechselmann[11] very early expressed the opinion, after critically reviewing the fatalities ascribed to arsphenamin from 1910 to 1913 including one case of his own, that nephritis due to mercury greatly increased the danger of toxic reactions by salvarsan presumably by interfering with the elimination of the drug with the consequent production of oxidation products of increased toxicity of which Ehrlich's "arsinoxid" was mentioned as a type. Schamberg[12] in this country has recently subscribed to the same view and believes that the large number of cases of delayed arsenical poisoning reported by Strathy, Smith and Hannah[13] may have been due to the fact that intensive treatment with mercury accompanied the injections of neoarsphenamin and especially since the authors themselves were of this opinion, as they state: "A few of the patients showed slight symptoms of mercurial poisoning, but mercury is known to be an irritant of the kidneys and in excessive doses to cause degeneration of the tubular epithelium, and it seems not at all unlikely that for this reason it acted as a predisposing factor."

Like in everything else, a conservative and well-balanced attitude is required in regard to this question of the influence of mercury upon the production of toxic reactions by the organic arsenicals. I am absolutely sure that mercury can be given before or during treatment with arsphenamin or neoarsphenamin without injury; on the other hand, I am equally sure that the administration of the usual doses of arsphenamin, neoarsphenamin and sulpharsphenamin in the presence of mercurial nephritis, as indicated by the presence of albumin and casts in the urine and possibly associated with the retention of urea and other nitrogenous products, may be fraught with danger and requires more than usual caution in dosage. Certainly there can be no reasonable doubt of the fact that injury of the kidneys by mercury, focal infection or any other agent to the extent of appreciably reducing the elimination of arsenic increases the danger and incidence of arsenical injuries; tying off the ureters greatly increases the toxicity of arsphenamin and other organic arsenical compounds, as shown experimentally by Voegtlin and his associates. But recent writers are not giving this subject of the influence of

mercury upon the toxic arsphenamin reactions as much emphasis as earlier writers. For example, Stokes and Ruedemann were unable to work out any relation between the administration of mercury and the incidence of jaundice and Moore and Keidel could observe no influence of mercury upon the incidence of arsphenamin dermatitis and allied reactions. In general terms, it may be stated that the importance of the etiological relationship between the administration of mercury and the toxic arsenical reactions has been overemphasized, although no one can deny that, when the administration of mercury or bismuth has preceded injections of arsphenamin or its substitutes or accompanies these, due care and caution must be exercised in the thorough and routine examination of the urine for albumin and casts, supplemented if necessary by an examination of the blood for urea, total non-protein nitrogen and creatinin and especially by a functional test as advocated by Lorenz and Bleckwerin[14] in order to avoid the grievous mistake of administering full doses of arsphenamin or neoarsphenamin in the presence of damaged kidneys with insufficient elimination.

The administration of the iodids, however, certainly does not appear to be important in relation to this question of toxic reactions by arsphenamin and its substitutes. As shown by Lucke and myself,[15] even very large doses of repeated intravenous injections into rabbits are without injurious effects upon the liver, kidneys and other organs. It is possible and, indeed, probable, that doses large enough to produce ptyalism, eruptions and depressive symptoms of patients may lower local resistance of the gums to mercury and bismuth and by general effects increase susceptibility to the minor reactions of the arsenicals, but there are no grave histological changes produced in the important internal organs as may occur upon the administration of mercury or bismuth.

Hypersensitiveness in Relation to Toxic Reactions by Arsphenamin and Neoarsphenamin.—Finally, one must consider the possibility of natural or acquired hypersensitiveness to arsphenamin, neoarsphenamin and other organic arsenical compounds as a possible cause of untoward reactions following the administration of these to human beings. Undoubtedly, hypersensitiveness to mercury, quinin, procain, iodoform and a few other drugs are known to occur and usually in the form of a natural hypersensitiveness rather than an acquired form due to the use of these drugs.

But before taking up this question, it may be well to define the terms employed, inasmuch as so much confusion exists in the terminology for these phenomena, a more complete discussion of the subject being found in the third edition of my book on "Infection, Immunity and Biologic Therapy." *Allergy* may be defined as a condition of unusual or exaggerated specific susceptibility to a substance which is harmless in similar amounts for the majority of members of the same species. *Anaphylaxis* is a form of allergy characterized by extreme susceptibility to protein agents; *hypersensitiveness* is a form of allergy characterized by extreme susceptibility to non-protein agents. Since the organic arsenical compounds are not protein substances, it is proper to speak of exaggerated susceptibility to them as hypersensitiveness; if, however, it is proven that arsphenamin or its substitutes injected into the blood are capable of uniting with the blood proteins and transforming them into a protein sufficiently "foreign" to the body to sensitize the tissues, then we could speak of these phenomena as being anaphylactic; but this has not been proven, and I believe that "hypersensitiveness" is the proper term to employ in the light of our present knowledge of the subject. *Intolerance*, however, is not the same as hypersensitiveness as defined. Intolerance is due to an accumulation of toxic substances (presumably of pentavalent

compounds of arsenic) in the tissues whereas in hypersensitiveness there may be no evidences of cumulative toxicity.

In the first place does natural hypersensitiveness to arsphenamin and its substitutes (presumably to the arsenic) exist? I have observed immediate reactions of the acute vasoparetic type ("nitritoid crisis") follow the first intravenous injection of 0.45 gm. of neoarsphenamin and personally suspect that these individuals were hypersusceptible to the drug, since the drug itself and method of administration could not be incriminated. Lesne and Dreyfus[16] in 1912 expressed the opinion that some individuals may be naturally hypersusceptible to arsenic, and Zieler[17] at about the same time stated that arsenical dermatitis may be due to a state of hypersensitiveness. All of the phenomena of true allergy in human beings show that the maximum effect is upon the smooth muscle of the body including that of the blood-vessels with the production of vasodilatation followed by cellular and serous exudation. Arsenic likewise produces vasodilatation by some vasculotoxic mechanism and I believe that the acute vasoparetic reaction ("nitritoid crisis") is solely an expression of this vasculotoxic effect of arsenic in individuals who have a natural or acquired hypersusceptibility to the effects of arsenic. The acquired form of this hypersensitiveness due to acquired allergic sensitiveness by reason of intracellular colloidal changes may be readily confused with intolerance due to accumulative toxic effects, but the mechanism is different from that of true hypersensitiveness as defined.

In the second place, may the lower animals be rendered hypersensitive to arsphenamin and its substitutes? All attempts to effect this by intravenous injections of the drugs alone have apparently failed as reported by Auer[18] and others until recently, when success has been claimed by Flandin and Tzanck. In like manner, all similar attempts to render the lower animals hypersensitive by injections of mercury, quinin, belladonna, iodoform, etc., have failed but these failures do not constitute an argument against accepting the possibility of acquired hypersensitiveness in human beings; they simply show that different animals vary in susceptibility and it is very well known that the lesions and symptoms of allergy vary greatly among different species of animals. Likewise, failure to passively transfer drug hypersensitiveness from human beings to the lower animals by injections of serum (passive allergy) does not constitute an argument against accepting the possibility of natural and acquired hypersensitiveness of human beings to drugs, including arsphenamin and its substitutes; the production of passive anaphylaxis of guinea-pigs by injections of the serums of human beings known to be anaphylactic to a protein agent is usually difficult to accomplish, and failure may be due to errors in technic or more likely because the allergic antibody is in or upon the sensitized body cells rather than free in the blood although in this connection mention may be made of the claims of successful passive transfer of allergies to guinea pigs by injections of sera from human beings hypersensitive to iodoform and antipyrin by Bruck[19] and Klausner.[20] Klauder,[21] however, failed to passively transfer to guinea-pigs hypersensitiveness to arsphenamin by injections of serum from a human being who showed all of the classical symptoms (asthma and eczema) of true allergic sensitiveness to both arsphenamin and neoarsphenamin.

Swift[22] claims to have succeeded in producing allergic sensitiveness of guinea-pigs by injecting them with mixtures of guinea-pig serum and arsphenamin, presumably by the production in the test tube of a new protein combination sufficiently "foreign" to sensitize and intoxicate the animals; but as previously stated, no one has yet succeeded in sensitizing any of the lower

animals by intravenous injections of the drugs unless it be Flandin and Tzanck[23] who claim to have successfully sensitized guinea-pigs with intracardiac injections of sulpharsenol in dose of 0.02 gm. They state that the first injection if slowly given produced no symptoms, or, at most, the animals remained motionless, curled up and appeared to be fatigued. A second intracardiac injection, made not less than three days later, and of $\frac{1}{10}$th to $\frac{1}{20}$th the first dose, induced what they regarded as allergic crises in two minutes from which the majority of animals recovered. The symptoms, as described by them, appear to me, however, as being possibly due to "anaphylactoid" phenomena as described by Hanzlik and Karsner[24] and the experiments require confirmation before one may accept them as true allergic reactions.

However, may human beings acquire hypersensitiveness as a result of injections of arsphenamin and its substitutes? The fact that guinea-pigs have not been generally successfully hypersensitized by injections of arsphenamin and neoarsphenamin does not by any means answer the question for human beings, because the latter are apparently more susceptible to sensitization by various substances than the lower animals with the possible exception of the guinea-pig by injections of horse serum. In 1911, Fischer,[25] Hoffmann and Jaffe,[26] Levens[27] and Swift expressed the opinion that human beings may acquire hypersensitiveness to salvarsan and at about the same time Staeubli[28] described a case of apparent acquired hypersensitiveness to sodium cacodylate yielding positive skin reactions, similar cases being reported by Kauffmann[29] and Stauble.[30] More recently Stuart and Maynard[31] and Guy[31a] have described cases of apparently acquired hypersensitiveness to arsphenamin among some patients who suffered with exfoliating dermatitis and describe well-marked skin reactions following the intradermal injection of dilutions of neoarsphenamin and arsphenamin varying from 1:1000 to 1:25,000.

Apparently, however, the reactions were not specific for arsphenamin or neoarsphenamin, that is, patients who developed hypersensitiveness to arsphenamin yielded positive skin reactions likewise to neoarsphenamin. Mook[32] had previously observed negative reactions when solutions of arsphenamin had been applied to abrasions of the skin and Moore and Keidel[33] have likewise observed negative cutaneous tests among some of their cases of dermatitis. Klauder,[34] however, observed positive cutaneous reactions following the application of 2-per cent. solutions of arsphenamin and neoarsphenamin to scratches on the arm of a marked case of apparent hypersensitiveness to these drugs with asthma and localized eczematous dermatitis of the hands and face.

It is difficult to reach a conclusion on this subject of acquired hypersensitiveness to arsphenamin and neoarsphenamin; it may be, as stated by Ullmann,[35] that, in cases suggestive of this state that there is deficient elimination and cumulative toxic effects rather than a true hypersensitiveness but I personally believe that hypersensitiveness may be acquired. Not infrequently patients who have had one or more courses of arsphenamin or neoarsphenamin suddenly or gradually begin to develop immediate or early toxic reactions after the intravenous injection of even small doses of neoarsphenamin; it is true that skin tests among these have been uniformly negative and that the effects may have been due to accumulative toxicity but this is hardly likely when nausea, vomiting, flushing, etc., develop almost immediately after the intravenous injection of 0.2 to 0.3 gm. of neoarsphenamin and when one may be reasonably sure that neither the drug nor method of administration are at fault.

In conclusion, brief mention may be made again of the opinions expressed by Stokes, Keidel and Moore to the effect that arsphenamin dermatitis, while not directly the result of hypersensitiveness to the drug, may be due to a state of anaphylaxis to bacterial or other foreign protein brought to the skin by means of the vasculotoxic effects of the arsenic of the drugs; these theories are discussed with more detail in Chapter LI.

CHAPTER XLVIII

ADMINISTRATION OF ARSPHENAMIN, NEOARSPHENAMIN AND SULPHARSPHENAMIN IN RELATION TO TOXIC REACTIONS

Errors in the administration of arsphenamin, neoarsphenamin and their substitutes employed in the treatment of syphilis have always been prominently mentioned as the cause of untoward effects and reactions. As I have already discussed in Chapter XLV, this subject is of particular importance in the administration of arsphenamin owing to the importance of physical

and physico-chemical factors greatly influencing the toxicity of this compound, but the methods employed for preparing and administering solutions of neoarsphenamin, sulpharsphenamin and other medicinal organic arsenicals are likewise of considerable practical interest and importance in relation to toxic reactions and therapeutic results.

In order to discuss this subject in a logical manner I shall endeavor to correlate the results of animal experiments with clinical experience and to present the matter in steps corresponding to the order in which the drugs are prepared for administration beginning with their keeping qualities as dispensed, the preparation of solutions, etc., and ending with their injection.

Stability or Keeping Qualities of Arsphenamin, Neoarsphenamin and Sulpharsphenamin. *Deterioration of Arsphenamin, Neoarsphenamin and Sulpharsphenamin Powders Exposed to Air.*—Arsphenamin, neoarsphenamin and sulpharsphenamin are usually dispensed in ampules from which the air has been withdrawn by vacuum production or in which it has been replaced by an oxygen-free gas as nitrogen or carbon dioxid. This precaution is for the purpose of preventing oxidation and other changes which increase the toxicity of the compounds. The physician, therefore, must carefully avoid using cracked ampules and especially those in which the powders have changed to a deep orange or brown color with decreased solubility.

As a matter of fact, however, perfectly dried and freely movable arsphenamin, neoarsphenamin and sulpharsphenamin powders exposed to the air at ordinary room temperature in open ampules do not quickly become toxic or change in trypanocidal or spirocheticidal activity. In 1916, Schamberg, Raiziss and I[1] reported that arsphenamin powder exposed to the air in open ampules from eighteen to forty-one days did not acquire increased toxicity for rats. Since then I have repeatedly tested the toxicity of different brands of arsphenamin powders kept in open ampules for from one hour to twenty-one days at ordinary room temperature and found only occasionally an increase of toxicity of some lots after an exposure of five or more days without any definite decrease in trypanocidal activity. Neoarsphenamin and sulpharsphenamin, however, are much less stable and have usually shown an increase of toxicity after two or three days exposure, although in some instances no change was apparent for ten or more days. It is to be carefully borne in mind, however, that these tests were conducted with rats injected intravenously according to the official method described in Chapter II and the results based upon the largest amounts of the drugs compatible with life, whereas with human beings it is entirely likely that the exposed compounds would prove much more toxic, as indicated by the severe reactions known to have been produced by the accidental administration of the drugs from cracked ampules in which the powders have been exposed for indefinite periods of time.

Not infrequently ampules are opened but the contents not dissolved for an hour or two, and the question arises whether or not it is safe to use arsphenamin, neoarsphenamin or sulpharsphenamin under such conditions. I believe that the danger of oxidation of the dried powders has been very much over-emphasized. Repeated and rigid animal tests have proved to me that these compounds do not acquire an increased toxicity when the powders are exposed to the air for an hour or two and I have repeatedly administered them by intravenous injection without any untoward effects whatsoever. Solutions exposed to the air deteriorate much more rapidly, as will be shortly discussed, but arsphenamin, neoarsphenamin and sulpharsphenamin in dried powder form can be safely used an hour or two after the ampules have been opened. An exposure of this duration does not result in any change in color,

solubility, toxicity or spirocheticidal activity of these compounds and undue haste in the preparation of solutions is unnecessary.

Deterioration of Arsphenamin, Neoarsphenamin and Sulpharsphenamin Powders Sealed in Vacuo.—Probably of even greater practical importance is the question of the keeping qualities of arsphenamin, neoarsphenamin and sulpharsphenamin properly sealed in ampules *in vacuo* or with an oxygen-free gas. Physicians not infrequently employ compounds one or more years old that have been kept in their offices or in pharmacies for long periods of time at ordinary room temperature and the matter of changes in toxicity and therapeutic activity of such compounds becomes one of considerable practical importance.

Roth[2] has reported that 25 to 30 per cent. of different lots of two brands of neoarsphenamin examined in the Hygienic Laboratory three years after the first tests showed changes of deterioration and that changes in solubility of neoarsphenamin may occur as early as forty-eight hours after manufacture. My own experiments with three different brands of neoarsphenamin kept at ordinary room temperature for a period of two years have not shown quite as high percentage of deteriorations as reported by Roth occurring in three years. From 5 to 12 per cent. of ampules, however, have shown changes in color to a deep orange or a change in solubility and a few of these showed a slight increase of toxicity for the rat in that the maximum tolerated dose was reduced from 0.280 to 0.350 gm. per kilo to 0.190 to 0.300 gm. per kilo. In no instance have all the ampules of any single lot shown this change but only a few ampules of certain lots. In other words, it would appear that deterioration may be due to defects in putting up the ampules and especially insufficient vacuum; likewise, in this connection, the question of the dryness of the powder is important and experience has shown tht neoarsphenamin, weighed out and ampuled on humid, rainy days with increased moisture in the air, are apt to deteriorate more rapidly and more frequently than perfectly dry products ampuled on dry, sunny days. The trypanocidal and spirocheticidal activities of the powders in such ampules, however, have shown no greater degree of change than the usual and expected differences, due to experimental error, because the degree of oxidation and other chemical change in the molecules has not usually progressed to the extent of reducing the parasiticidal properties as may occur, however, when solutions are exposed to the air until profound changes have occurred.

Arsphenamin is much more stable. Roth has observed practically no changes in the physical appearance, solubility or toxicity of different brands kept in the Hygienic laboratory for three years and my own experience with different lots from one laboratory kept for as long as seven years has been the same. I have repeatedly determined the toxicity and trypanocidal activities of arsphenamin from one to three and a half years old without detecting any degree of change beyond slight and irregular differences due to experimental error. In a fewer number of spirocheticidal tests employing rabbits infected intratesticularly with *Spirochæta pallida*, no changes were discovered with products four years old.

It is well, however, for physicians, clinics, hospitals and pharmacies to avoid overstocking with these compounds in order that it may be a matter of routine to use fresh rather than aged arsphenamin and neoarsphenamin and especially the latter.

I do not know how sulpharsphenamin compares with arsphenamin and neoarsphenamin in these respects, since this compound has been in use for only about two years. At this writing it may be stated, however, that I have found no evidences of color change, solubility, toxicity and trypanocidal activity of different lots of two brands kept at ordinary room temperature for twelve months.

Deterioration of Preserved Solutions of Arsphenamin (Lowy).—Since arsphenamin is quite a stable substance even in solution, provided all oxygen has been removed, Lowy[3] has advocated the clinical use of prepared solutions in order to facilitate the administration of the drug by those physicians who have neither the time nor the facilities for making up their own solutions.

When properly prepared with a high degree of vacuum to remove oxygen, these solutions can be kept for six months or longer without changes in physical appearance or increased toxicity. But I have observed that they may undergo a gradual reduction in trypanocidal activity and the Hygienic laboratory has placed a *time limit of six months upon them dating from the time of their preparation.* In other words, solutions of arsphenamin prepared according to Lowy's method are perfectly satisfactory for at least six months and serve a very useful purpose for aiding in the administration of the drug by those physicians who inject the compound only occasionally, but after six months changes in toxicity, and more especially, a reduction of therapeutic activity may occur. These solutions do not appear to be more toxic for the rat than freshly prepared solutions and clinically they are just as satisfactory, as indicated by the reports of Stetson[4] and others.

Solutions of arsphenamin (Lowy) should be kept in a cold place; at temperatures higher than 75°F. deterioration is more rapid. Freezing does no harm if the solution is allowed to thaw at a temperature not higher than 70°F.

Menstrum Employed for Preparing Solutions in Relation to Toxic Reactions.—Since the earliest days of arsphenamin therapy, some of the toxic reactions have been ascribed to the water or saline solution employed instead of to the drug. Inasmuch as the ordinary dose of this compound is administered by intravenous injection dissolved in 100 to 200 c.c. or more of water, saline solution, etc., the condition of the menstrum is not an unimportant matter; within recent years, however, the subject has not commanded as much attention as formerly, since neoarsphenamin and sulpharsphenamin administered in concentrated solutions have largely replaced arsphenamin in the treatment of syphilis and thereby reduced the importance of those toxic reactions possibly due to foreign substances and especially organic matter in the menstrum employed.

Microörganisms and Their Products and Other Matter in the Menstrum, in Relation to Toxic Reactions.—When *sterile* water or saline solution is employed no part of the toxic reaction can be ascribed to living bacteria; sterilization may also be counted upon to destroy bacterial toxins, so that one cannot subscribe to the original "Wasserfehler" theory of Wechselmann[5] that the febrile and gastro-intestinal reactions were due to *living* hemolytic bacteria and their toxins in the water or saline employed when the solutions are sterilized just before use.

But sterilization does not remove the possibility of reactions being caused by dead bacteria and various yeasts and molds and their disintegration products that may be present. It is well known that the intravenous injection of as few as 25,000,000 dead colon or typhoid bacilli in the form of a vaccine may elicit a sharp reaction of fever and rigors; these effects are not due to living bacteria and toxins, but rather to the disintegration products of the organisms and the colloidal disturbances which their injection produces in the form of the so-called non-specific protein reaction. Now *stale* water, distilled or otherwise, frequently and indeed usually, contains a surprisingly large number of bacteria and yeasts unless due precautions are taken to prevent contamination after distillation. Distillation kills bacteria, destroys their toxins and largely leaves behind the products of their disintegration; when such water is carefully protected against subsequent contamination, the possibility of "protein" toxic reactions is greatly reduced but not infrequently solutions of arsphenamin and its substitutes are prepared with stale distilled water in which precautions against contamination are very inadequate as, for example, the use of the different commercial brands of

bottled distilled water. It is true that such water can be and usually is, sterilized before use; this, however, only kills the organisms but does not remove them and I believe that the intravenous injection of a large volume of such water as 80 to 300 c.c., may elicit a reaction of fever, nausea, rigors, etc., in exactly the same manner as the intravenous injection of a sterile bacterial vaccine.

Yakimoff and Yakimoff[6] have stated that salvarsan injected into animals along with various dead bacteria is more toxic than salvarsan alone; that is to say, when such bacteria are present, a smaller dose of salvarsan will suffice to kill the animal than when no bacteria are present. McIntosh, Fildes and Dearden[7] have shown in a clear and convincing manner experimentally and clinically that bacteria-free saline solution is non-toxic, whereas the addition of different varieties of bacteria to non-toxic saline before sterilization. renders it toxic due to the presence of the dead bacterial bodies themselves and not to endotoxins derived from them. Matzenauer,[8] however, claims that water containing as many as 1,700,000 germs per cubic centimeter did not increase the toxicity of salvarsan and believes that toxic reactions are due primarily to the drug itself. In 1916, Schamberg, Raiziss and I[9] showed that arsphenamin dissolved in freshly distilled water was less toxic for rats than solutions in stale distilled or non-distilled water.

Therefore, one of the chief purposes of using *freshly* distilled water for preparing solutions of arsphenamin and its substitutes for intravenous injection, is to remove dead microörganisms and their products; Ehrlich always insisted upon this with justice and reason. *Freshly* sterilized tap water containing but few bacteria is much to be preferred to a *stale* sterilized distilled water and it is surprising how few bacteria are usually found in fresh tap water. Many physicians have reported that they have employed fresh sterilized tap or spring water with as much success as sterilized distilled water and this is readily understood, provided the raw water is not unusually rich in inorganic salts or organic matter.

It is true that this subject is not as important in relation to the injection of concentrated (10 to 20 c.c.) solutions of neoarsphenamin or sulpharsphenamin as it is to the intravenous injection of arsphenamin dissolved in 80 to 300 c.c. of water or saline solution; but the intravenous injection of even 10 to 20 c.c. of stale water containing dead bacteria and yeasts may conceivably produce reactions. At any rate the matter of the purity of the water or saline solution from the standpoint of bacterial proteins and other organic matter is not without practical importance, and here it may be stated that solutions should be prepared only with water or saline that is not only sterile but free or nearly so of dead microörganisms and their products and of other organic matter; therefore, only freshly distilled water or distilled water hermetically or otherwise sealed against subsequent contamination should be used for the intravenous injection of arsphenamin and its substitutes.

Inorganic Impurities in Water or Saline, in Relation to Toxic Reactions.— Distillation of water also removes a large part of inorganic salts and this may be an added advantage in those districts in which the water is unusually rich in various salts of calcium, magnesium, etc. Gonder, at the request of Ehrlich, conducted experiments on the toxicity of salvarsan solutions to which small amounts of calcium and magnesium salts commonly found in tap water, were added and states these increased the toxicity of the drug for mice and other animals. Emery believed that contamination of water with copper, lead or salicylates from the distilling apparatus increased the toxicity of salvarsan solutions. Matzenauer believed that alkali dissolved out of the glass container may be a factor in the production of reactions, etc.

These observations led Ehrlich and others to advise the use of water freshly distilled from glass apparatus and various kinds have been devised to enable physicians to distil water in their offices. Personally I have never

been convinced that all-glass apparatus was necessary and, so far as my animal tests and clinical experience are concerned, water distilled from tin-lined apparatus has always been just as satisfactory, provided the boiling and condensing apparatus is occasionally cleaned to remove encrusted salts. In my opinion the primary purpose of using freshly distilled water is to avoid an excess of organic matter and especially the products of dead organisms; the usual amounts of inorganic salts present in water are of much less importance.

Sterility of Arsphenamin, Neoarsphenamin and Sulpharsphenamin.—In connection with this subject of bacterial contamination in relation to toxic reactions, the question may arise regarding the sterility of the drugs themselves. A few years ago I cultured aërobically and anaërobically 100 different lots of arsphenamin and 100 different lots of neoarsphenamin and also made mouse inoculation tests for tetanus spores. All of the arsphenamin cultures proved sterile; ten lots of neoarsphenamin showed the presence of bacteria, eight of these cultures being *B. subtilis* and two a white staphylococcus. All mouse tests for tetanus proved negative. Arsphenamin, therefore, has proved more bactericidal than neoarsphenamin; this is true not only of the dried powder but of the solutions as well, as will be shortly discussed.

These results, however, warrant the conclusion that when arsphenamin and neoarsphenamin are tubed in a careful and aseptic manner bacterial contamination is quite uncommon and in this connection it may be stated that no cases of bacterial infection have yet been ascribed to the injection of these compounds; of course, this statement does not refer to local skin infections due to faulty technic in injection. Since sulpharsphenamin is frequently administered by subcutaneous or intramuscular injection, the question of bacterial contamination is of greater practical importance in relation to the local reactions produced; up to the present time, however, my cultures of twenty-two different lots of the sulpharsphenamines prepared in two different laboratories have proved sterile in all except two; apparently this product is less bactericidal than arsphenamin. At any rate, it does not appear that either local or general bacterial infections have been ascribed or traced to the drugs themselves and it is certain that they do not contain enough living bacteria to produce the protein reactions.

Bactericidal and Bacteriostatic Activity of Solutions of Arsphenamin and Neoarsphenamin.—And now the question may also arise regarding the bactericidal properties of solutions of arsphenamin and its substitutes, not so much in relation to their use in the treatment of bacterial infections considered in Chapter VII, as in relation to the autosterilization of solutions before administration.

With the assistance of Miss Mary Trist, I have studied this question with much interest employing the Hygienic laboratory phenol coefficient method and my bacteriostatic test previously described.[10] Arsphenamin dissolved in cold water in the usual proportions of 0.6 gm. to 80 to 150 c.c. followed by neutralization, is not appreciably bactericidal in 15 minutes, but if boiling hot water is employed a considerable degree of bactericidal activity for staphylococci is apparent, largely due to the heat in addition to the feeble activities of the alkali and drug itself. In other words, *the use of very hot water for the preparation of solutions of arsphenamin has the distinct advantage of greatly increasing the chances of infecting a sterile solution in case the glassware or water had become accidentally contaminated.*

One per cent. solutions of neoarsphenamin and sulpharsphenamin were not bactericidal but concentrated solutions like 0.6 gm. dissolved in 6 c.c. of water were frequently completely bactericidal in 5 minutes, almost always in 15 to 30 minutes and may be counted upon to bring about a con-

siderable degree of bactericidal activity in case the water or glassware has become contaminated.

Water versus Saline Solution in Relation to Toxic Reactions.—The question has frequently been raised whether saline solution alone was responsible for mild febrile reactions or "salt fever," since Marschalko[11] in 1911 stated that the percentage f sodium chlorid present in the saline solution was a matter of great importance. Bingel[12] found that fever was elicited in man by subcutaneous and intravenous injections of normal saline solution, but that the result was not influenced by alterations in the concentration of sodium chlorid. Wechselmann has stated that the occurrence of fever was largely diminished by the use of Ringer's solutions, but McIntosh, Fildes and Dearden[13] found that toxic reactions were very little less frequent after intravenous injections of Ringer's solution than after saline and that alterations in the concentration of sodium chlorid did not affect toxic reactions. Indeed, quite recently, Wiesenack[14] has advocated the use of hypertonic saline solution for the administration of arsphenamin, stating that it reduces the incidence of reactions.

In numerous toxicity and trypanocidal tests employing rats, I have never been able to observe that solutions of arsphenamin and neoarsphenamin in water varied from duplicate solutions in saline solution, although it is to be borne in mind that tests of this kind do not disclose the incidence of minor reactions as fever and rigors which may be elicited in human beings. White rats can stand intravenous injections of enormous amounts of distilled or tap water and physiological saline solution without the production of jaundice, hemoglobinuria or other discoverable evidences of toxic reactions; as much as 50 c.c. per kilo corresponding to 3000 c.c. per 60 kilos or the weight of an average sized adult human being have been injected without influence upon the lives of these animals. But as just stated, the intravenous injection of water or saline solution may produce reactions in man which are not discernible in the rat, although it does not appear that physiological saline solution is any more toxic than an equal amount of distilled water per kilogram of weight. The intravenous injection of either usually produces a mild leukocytosis which may be accompanied by slight fever if large amounts are administered. In rabbits, the intravenous injection of 0.5 c.c. of water per kilo generally produces a slight leukocytosis with an increase of the polymorphonuclear leukocytes and an increased rectal temperature of 1° or 2°F. within two to four hours after injection, and, curiously, in numerous experiments, I have observed that the injection of freshly distilled water produces slightly greater reactions than tap water.

While saline solution does not appear to increase the incidence of toxic reactions, the question now arises whether it reduces them. I believe it may be stated in a broad and general manner that, when arsphenamin, neoarsphenamin or sulpharsphenamin are injected intravenously dissolved in 100 c.c. or more of water or saline solution, the latter may reduce the incidence of reactions and should be employed because intravascular hemolysis is prevented or reduced. As discussed more fully in Chapter XLV neoarsphenamin and sulpharsphenamin are not hemolytic but arsphenamin is hemolytic. Furthermore, when the usual dose of neoarsphenamin or sulpharsphenamin is dissolved in 10 to 15 c.c. of water the solutions are not hemolytic, but solutions of neoarsphenamin or sulpharsphenamin in 30 c.c. or more of water are not isotonic and may produce hemolysis. Solutions of the monosodium and disodium salts of arsphenamin in both water and saline solution are hemolytic, but the latter are much less so than the former. *Therefore, when neoarsphenamin and sulpharsphenamin are administered in concentrated solutions, as they may well be, sterile freshly distilled water may be employed, but when these and arsphenamin are administered in dilute solutions it is better to use a sterile* 0.5*-per cent. saline solution prepared of chemically pure sodium chlorid and freshly distilled water.*

Glucose Solutions in Relation to Toxic Reactions and Therapeutic Activity. A 4.5- to 4.7-per cent. solution of chemically pure glucose in distilled water

is isotonic and Fleig[15] states that solutions of arsphenamins in 4.5-per cent. glucose are less toxic for both rabbit and man by intravenous injection than solutions in water. Isotonic solutions of lactose (9.2- to 9.5-per cent.) likewise reduced toxicity to some extent, but not as much so as 4.5-per cent. solutions of glucose. Hypertonic glucose solutions (10-per cent.) also decreased toxicity, but best results were observed with the isotonic solutions.

The results of my own experiments employing rats have yielded confirmation to these observations. In the first place, chemically pure glucose is but very slightly toxic. I have injected rats intravenously with doses as high as 25 grams per kilo of body weight without fatal results and this dose corresponds to 1500 grams for an average adult of about 132 pounds.

Solutions of the disodium salt of arsphenamin in water, killing rats within forty-eight hours after intravenous injection is dose of 0.140 gm. per kilo of weight, have been borne indefinitely in doses as high as 0.220 gm. per kilo administered in 4.5- to 5-per cent. solutions of glucose in water. Numerous experiments have yielded similar results in that the use of glucose solution has reduced the toxicity of arsphenamin for these animals. Furthermore, my trypanocidal tests have shown that the therapeutic activity of arsphenamin is not altered (increased or decreased) in isotonic glucose solution and from the standpoint of animal tests it would appear advisable to employ sterile 4.5- to 5-per cent. solutions of chemically pure glucose in distilled water (sterilized in an Arnold and not autoclaved) for the administration of arsphenamin, although I am not convinced that the incidence of reactions in human beings is materially lessened as compared with solutions in plain isotonic saline.

I am quite sure that there is no advantage in using glucose solution for the intravenous administration of concentrated solutions of neoarsphenamin and sulpharsphenamin, although it is stated that solutions of the latter, as well as of soluble sodium and potassium tartrobismuthate in glucose solutions, are less painful when injected subcutaneously or intramuscularly. Duhot[16] employs a 50-per cent. solution of glucose for intravenous injections and states that it prevents the precipitation of arsphenamin by the plasma and thereby reduces its toxicity. Cheinisse[17] likewise employs hypertonic solutions (25- to 50-per cent.) for the administration of arsphenamin to hypersensitive patients, and states that this plan enabled him to continue the treatment of five individuals who previously had been totally unable to tolerate the drug. Pranter[18] employs 10- to 20-per cent. solutions; Steinberg[19] administers 0.1 to 0.2 gm. doses of both arsphenamin and neoarsphenamin in 30 c.c. of 30-per cent. solutions of Merck's glucose and states that not only are the toxic reactions reduced but that spirocheticidal effects are increased. As stated above, I found that 5-per cent. solutions had no effect upon trypanocidal activity, but since glucose reduces toxicity by lowering the rate and degree of reduction of arsphenamin and neoarsphenamin by oxidation, I am inclined to think that Steinberg is in error and that the effect of large amounts of glucose would be to reduce the toxicity of the drugs for the spirochetes, that is, reduce therapeutic activity, in the same manner as it reduces toxicity for body cells.

Gelatin Solutions in Relation to Toxic Reactions and Therapeutic Activity.—In Chapter XLV I have already discussed the work of Oliver and his associates upon the influence of gelatin in reducing the toxicity of arsphenamin presumably by protecting the corpuscles against agglutination and hemolysis.

In my experiments it was found that the maximum tolerated dose of gelatin, dissolved in sterile distilled water but *not autoclaved*, was approximately 6 to 7 grams per kilo; solutions *autoclaved* for 20 minutes at 15 pounds pressure were less toxic, the maximum tolerated dose being more than 10 grams per kilo. From the standpoint of toxicity it would appear, therefore, quite safe to inject human beings with 0.5- to 2-per cent. solutions intravenously.

Unquestionably solutions of disodium arsphenamin in 1- to 2-per cent. solutions of gelatin in sterile distilled water are sometimes slightly less toxic for rats by intravenous injection than solutions in plain water and in my experiments solutions of arsphenamin in autoclaved 2-per cent. solutions of gelatin were less toxic than in unheated solutions of

gelatin. But gelatin solutions of arsphenamin, as well as of neoarsphenamin, have generally (but not always) been slightly less trypanocidal and spirocheticidal in my tests than solutions in water and I believe this constitutes an objection to the use of gelatin solutions for the administration of arsphenamin in the treatment of syphilis.

Furthermore, I am not at all sure that 0.5- to 2-per cent. gelatin solution reduces the incidence of toxic reactions in human beings; indeed, it is my impression that the intravenous injection of 100 to 150 c.c. of these solutions has frequently yielded reactions of slight fever, chilliness and malaise in from one to three hours after injection that were caused by the gelatin rather than the drug.

Influence of the Temperature of the Water or Saline Solution Employed upon Toxic Reactions.—The possible influence of the temperature of the menstrum employed for the preparation of solutions of arsphenamin is of considerable practical importance, because some preparations are not freely soluble in cold water, rendering necessary the use of hot water; indeed, it is not an uncommon practice to add the drug to water boiling freely over a flame and I have myself usually employed this method. Since neoarsphenamin and sulpharsphenamin are freely soluble in cold water, there is no necessity for using hot water although the influence of the latter upon toxicity is not without interest since some physicians employ hot water.

Lake[20] has reported that two different brands of arsphenamin dissolved in cold water and alkalinized in the usual manner killed 17 per cent. of rats within forty-eight hours in dose of 0.100 gm. per kilo by intravenous injection; solutions prepared with boiling hot water gave identical results, so that the use of boiling hot water for preparing solutions had no influence upon toxicity. When, however, the cold and hot solutions were placed in a boiling water bath for five to sixteen minutes, cooled and alkalinized, the toxicity was found to be increased, since 65 to 70 per cent. of the animals succumbed. Hunt,[21] however, found that solutions prepared with cold water and alkalinized followed by heating to 40° to 60°C. for a few minutes rendered the drug less toxic. The results of my experiments in this field, which have been quite numerous with different brands of arsphenamin and neoarsphenamin and employing rats injected intravenously, may be summarized as follows: (*a*) Arsphenamin dissolved in water at 60°–70°C. and boiling hot water, followed by cooling and alkalinization, was not any more toxic and possessed the same trypanocidal activity as solutions prepared in cold water. (*b*) Solutions prepared in hot or cold water followed by boiling for more than 5 minutes, cooling and alkalinization were usually rendered more toxic. (*c*) Solutions prepared in hot or cold water, alkalinized and then boiled were rendered still more toxic, that is to say, alkalinized solutions are rendered more toxic by heating than acid solutions. (*d*) Neoarsphenamin and sulpharsphenamin dissolved in boiling hot water were usually (not always) more toxic than solutions in cold water. (*e*) Solutions of neoarsphenamin and sulpharsphenamin boiled for five minutes or longer were usually rendered more toxic and less trypanocidal.

From the practical standpoint, therefore, this subject may be summarized as follows: (*a*) Arsphenamin may be dissolved in boiling hot water without any increase in toxicity or loss in therapeutic activity. (*b*) As soon as the solution is made, which should not require more than a few minutes, it should be allowed to cool. (*c*) After alkalinization the solution may be warmed or maintained at body heat without increase of toxicity. (*d*) Neoarsphenamin and sulpharsphenamin are least toxic when dissolved in cold water and deteriorate more rapidly than arsphenamin at high temperatures. To the best of my knowledge, solutions of arsphenamin prepared with hot water are not any more toxic for human beings than solutions prepared in cold water; indeed, the reverse is probably true, since arsphenamins difficulty soluble in cold water are chemically purer than those freely soluble in cold water. But solutions of neoarsphenamin in hot water may be more toxic than solutions in cold water; I know of one instance in which three cases of dermatitis were regarded as probably due to the administration of neoarsphenamin dissolved in hot water. However, since neoarsphenamin and sulpharsphenamin are freely soluble in cold water, there is no advantage in using hot water.

Use of Alcohol in the Preparation of Solutions of Arsphenamin, in Relation to Toxic Reactions.—One difficulty in preparing solutions of those arsphenamins not freely soluble in cold water is the formation of gelatinous masses which require an undue amount of shaking to effect complete solution. By placing the powder in a dry cylinder and thoroughly moistening with 1 or 2 c.c. of pure ethyl alcohol, quick solution is usually accomplished with cold or warm water, or saline solution with much less shaking. Lake has found in the Hygienic Laboratory that solutions prepared in this manner are sometimes appreciably less toxic than solutions made up in the shortest possible time with hot water. My own experience has been similar; toxicity for rats by intravenous injection has never been increased and in some instances has been somewhat less. Trypanocidal activity has never been altered. I have also administered arsphenamin prepared in this manner to human beings with no increase of toxic manifestations and regard the method as quite satisfactory for effecting solutions of those arsphenamins not freely soluble in cold water. I cannot say, however, that the results clinically are any better than solutions prepared with boiling hot water, as described in Chapter LVIII, but there is no danger of rendering the solutions more toxic by undue or prolonged heating and the method can be recommended for clinical use. The alcohol appears to increase the solubility of arsphenamin, not by dissolving it, but by penetrating throughout and moistening the dry powder. When water is added and the container quickly shaken, no gelatinous masses form as in the case when water alone is employed, these masses being the principal cause of delay in making solutions.

Solubility of Arsphenamin and Neoarsphenamin in Relation to Toxicity.—As previously stated, the less soluble brands of arsphenamin are not any more toxic than those readily soluble in cold water if simple precautions are taken against too much shaking of the solutions and overheating. From the chemical standpoint these arsphenamins are regarded as being chemically purer than those readily soluble in cold water.

But this is not true of neoarsphenamin. Solutions of this drug in water which are cloudy or opalescent are almost invariably more toxic for the lower animals and man than perfectly clear solutions. Not even filtration of the former through sterile paper or cotton removes the toxic factors and it is extremely important clinically to guard against the intravenous injection of either neoarsphenamin or sulpharsphenamin unless the solutions are readily made without undue shaking and are crystal clear. As previously stated, neoarsphenamin tends to deteriorate in the ampules and one sign of this change is decreased solubility. Roth[22] has drawn particular attention to the increased toxicity of incompletely soluble neoarsphenamin for rats due, probably, more to the physical state of the product itself than to excessive shaking; I have been able to confirm his observations and, in addition, have received numerous reports from physicians of severe reactions following the intravenous injection of cloudy solutions of neoarsphenamin which were rendered almost clear by filtration. Roth states that incompletely or slowly soluble products are dangerous, even if filtered. In 1918 to 1920 these products were much more commonly met with than at present; manufacturers have been able to perfect their products in this regard, but the change may occur after the product reaches the physician as a result of deterioration and due care must be exercised against their intravenous administration.

Concentration of Solutions of Arsphenamin and Neoarsphenamin in Relation to Toxic Reactions.—The concentration of solutions of arsphenamin bears an important relation to toxicity for both man and the lower animals; the concentration of solutions of neoarsphenamin and sulpharsphenamin is

much less important. The reason for this is ascribed to the importance of physical factors in relation to the toxic effects of solutions of arsphenamin, such as the reaction, viscosity, etc., as influencing the occurrence or physicochemical reactions like hemagglutination, hemolysis, precipitation of plasma proteins and of drug, etc., as solutions come in contact with the blood.

The subject of concentration of solutions is, therefore, intimately related to the rate of injection, because the amount of drug mixed with the blood in the same length of time may be altered by either factor. But when solutions of arsphenamin of different concentrations are rapidly injected, it has been shown experimentally that the higher concentrations may be more toxic than dilute solutions.

In 1916, Schamberg, Raiziss and I showed that alkalinized solutions of arsphenamin in solutions as concentrated as 0.060 gm. in 2 c.c. of water per kilo of weight, corresponding to 0.6 gm. per 20 c.c., were not any more toxic for rabbits by intravenous injection than dilute solutions, but the injections were given slowly with a gauge No. 26 needle, about three to five minutes being consumed in the administration. Roth has observed that 1-per cent. acid solutions of arsphenamin were approximately twice as toxic for rats as 0.5-per cent. solutions when both were injected at the rate of 1 c.c. in two minutes. Experiments with alkaline solutions administered at the same rate showed that toxicity was but slightly greater as the concentration was increased from 0.5-per cent. (0.6 gm. in 120 c.c. water) to 2-per cent. (0.6 gm. in 30 c.c. water). Fleig, in 1914, also showed that concentrated solutions of arsphenamin sometimes increased the toxicity of the compound and Ehrlich still earlier observed the same effects.

Lake states that a study of the extensive data available in the Hygienic Laboratory, on the clinical use of arsphenamin, showed that reactions seldom occurred when the dilute solution was used, even when the rate of injection was fairly rapid, and that, conversely, even a fairly concentrated solution seldom caused trouble when the rate of administration was slow. The reports showed, however, that it was in clinics where concentrated solutions were used, that most reactions occurred. These observations induced Dr. McCoy, Director of the Hygienic Laboratory, to issue a warning against the use of too concentrated solutions,[23] a concentration not greater than 0.5-per cent. being advised (corresponds to 0.6 gm. in 120 c.c. of water or 20 c.c. for each 0.1 gm.) with the caution that due attention be paid to the rate of injection to guard against too rapid intravenous administration. On the other hand, Nelken[24] considers that concentrated solutions given rapidly are as safe as the more dilute solutions given slowly, and Pusey[25] states that, while it is true that animal experiments have shown arsphenamin to be less toxic when well diluted, the necessity for highly dilute solutions arises only when arsphenamin is unusually toxic.

The influence of concentration is, therefore, far greater with acid solutions of arsphenamin than with those properly alkalinized. Two deaths from arsphenamin brought to my attention were due to the physicians administering 0.4 to 0.6 gm. in 15 to 20 c.c. of water by syringe injection in mistake for sulpharsphenamin. On the other hand, I know of physicians who have injected dilute acid solutions (0.6 gm. in 200 to 300 c.c. of water) without serious reactions; I am sure that only the factor of dilution in these instances averted serious and even fatal reactions.

With properly alkalinized solutions of good arsphenamin, however, the difference in toxicity between 2- and 0.5-per cent. solutions is usually slight or not discernible at all in both the lower animals and man providing that the injections are given *slowly*. I commonly administer 0.4 gm. of disodium arsphenamin in a total of 25 c.c. in a syringe fitted with a No. 22 needle and requiring at least two minutes by the watch with no more reaction than 0.4 to 0.6 gm. in 80 to 120 c.c. by gravity injection. However, if any solu-

tion accidentally infiltrates the perivascular tissues, the concentrated solution produces more reaction than the dilute solution and, since it is difficult to control oneself to give the injection slowly by syringe, I believe it is better routine practice to follow the plan of administration of dilute solutions by gravity injection.

With neoarsphenamin and sulpharsphenamin, however, the influence of concentration and rate of injection are of much less importance, as previously stated. Rats injected intravenously with either compound at the rate of one cubic centimeter per two minutes bear 4-per cent. solutions (corresponding to 0.9 gm. in 22.5 c.c.), as well as 1-per cent. solutions, and the same is true of human beings, even when the concentrated solutions are given by a syringe. It is my practice to administer both compounds by intravenous injection dissolved in not more than 10 to 15 c.c. of water. Indeed, abundant clinical experience has shown that 0.6 and even 0.9 gm. of neoarsphenamin dissolved in 2 c.c. of water (30- to 45-per cent. concentrations) may be injected with a syringe with perfect safety, although a small needle (about gauge No. 22) is advisable to guard against too rapid injection. It is clearly established, therefore, that neoarsphenamin and sulpharsphenamin may be safely administered in concentrated solutions and that dilute solutions injected by gravity are unnecessary.

Influence of Shaking Solutions of Arsphenamin and Neoarsphenamin, in Relation to Toxicity and Therapeutic Activity.—Oxidation of solutions of arsphenamin and neoarsphenamin produces aminohydroxyphenylarsenoxid ("arsenoxid"), which Ehrlich and Hata have shown increases the toxicity of the solutions; for this reason Ehrlich and his collaborators have always warned against unnecessary and excessive shaking of solutions and have advised their immediate injection.

Within recent years more definite experimental data have become available on the influence of shaking solutions of arsphenamin and neoarsphenamin in the air and much of it possesses direct clinical interest and application.

Roth,[26] who was first to study this problem, showed that shaking alkalinized 2-per cent. solutions of arsphenamin for one to ten minutes in cylinders, in contact with an equal volume of air, at the rate of approximately 230 excursions per minute, produced color changes in the solutions and increased their toxicity for rats about 60 per cent. However, this is not of great practical interest, because it is seldom necessary to shake solutions of arsphenamin after the addition of the alkali for more than a few seconds, although Roth states that he has worked with some samples which, upon the addition of normal sodium hydroxid to their watery solutions, formed rather dense precipitates that required considerable shaking, to produce clear solutions.

Of far more practical interest is the effect of shaking acid solutions of arsphenamin, that is, the amount of shaking required to dissolve the powder in water or saline solution. According to Voegtlin and Smith,[27] arsphenamin is exceedingly stable toward atmospheric oxygen, the addition of alkali leading to a rapid increase in the rate of oxidation roughly inversely proportionate to the hydroxylion concentration. Hunt[28] also states that aeration of acid solutions of arsphenamin for from two to four hours did not result in increased toxicity for rats in his experiments. But in the experiments of Schamberg, Raiziss and myself[29] with five different brands or arpshenamin it was found that shaking 2 per cent. acid solutions for one and ten minutes followed by alkalinization sometimes resulted in an increased toxicity for rats injected at the uniform rate of 1 c.c. per two minutes. The increase in toxicity, however, was not quite as great in some experiments as observed when the alkalinized solutions were shaken.

Neoarsphenamin undergoes a similar but even more marked change when solutions are shaken in air. According to Roth, shaking 4-per cent. solutions for ten minutes may increase the toxicity four-fold even when the solution has undergone little or no color change. Schamberg, Raiziss and I have observed similar results with the products of three different laboratories.

Roth has also shown that the color and toxicity changes were due to aeration, since shaking alone in the absence of air produced no changes. Schamberg, Raiziss and I found that the oxygen requirements of shaken solutions of both arsphenamin and neoarsphenamin

were decreased, indicating that oxidation had occurred. With more prolonged shaking it is probable that oxidation would have been more marked accompanied by a decrease in toxicity as "arsenoxid" is oxidized with the formation of m-amino-p-hydroxy-phenylarsonic acid, as apparently occurs when solutions of arsphenamin or neoarsphenamin are allowed to stand for long periods of time in contact with air.

Schamberg, Raiziss and I also determined the effect of shaking solutions of arsphenamin and neoarsphenamin upon trypanocidal activity, that is to say, upon their toxicity for parasites. Rats were employed infected with *T. equiperdum*, the drugs being administered twenty-four hours later by intravenous injection, as described in Chapter X. Voegtlin and Smith[30] state that the trypanocidal activity of arsphenamin is due to the formation of "oxids" and that the administration of preformed "oxid" in the form of "arsenoxid" exerts a quicker and greater trypanocidal effect than injections of arsphenamin itself. Some confirmation of this hypothesis is given by the results of our shaking experiments. Not infrequently the solutions after shaking one minute were more trypanocidal than unshaken solutions, although shaking for ten minutes was sometimes followed by a decrease in trypanocidal activity, probably the result of further oxidation to pentavalent compounds. Nothing can be stated, however, regarding the influence of shaking solutions of arsphenamin and neoarsphenamin upon toxic reactions in human subjects, although there is no reason why the results observed with rats may not apply except that the effects in human beings may not be discernible because the doses administered per weight in the treatment of syphilis are so much smaller than those given rats in the above mentioned experiments. As a matter of fact, additional experiments which I have conducted with acid and alkalinized solutions of arsphenamin and solutions of neoarsphenamin in exactly the same manner except that the dose of arsphenamin was 0.010 gm. per kilo (corresponding to the usual 0.6 gm. dose for the human being) and neoarsphenamin in dose of 0.015 gm. per kilo (corresponding to the usual 0.9 gm. dose) had absolutely no toxic effects. Doubtless the same changes occurred, but the dose was so small that toxic effects were not apparent and I believe the same occurs in the majority of human subjects. From the practical standpoint, therefore, in relation to the treatment of syphilis, the subject may be summarized as follows: (*a*) An undue amount of shaking of solutions of arsphenamin in water may increase toxicity to a slight extent; therefore, with the less soluble arsphenamins it is better to use hot water or moisten the powder with 2 c.c. of alcohol followed by the use of cold water, as previously described. (*b*) After alkalinization the solution should not be shaken more than the few seconds required for dissolving the precipitate. (*c*) Solutions of neoarsphenamin should not be shaken for more than the few seconds generally required. If any neoarsphenamin requires a minute or more of vigorous shaking for effecting solution, it should not be used as the injection of such compounds is likely to produce toxic reactions and especially if the solutions are not quite clear.

Similar experiments with sulpharsphenamin have not been reported, but I believe from a few experiments of my own that this compoud behaves in much the same manner as neoarsphenamin when solutions in water are vigorously shaken in contact with air.

Influence of Exposure of Solutions of Arsphenamin and Neoarsphenamin to the Air in Relation to Toxicity.—Naturally solutions of arsphenamin, neoarsphenamin and sulpharsphenamin allowed to stand exposed to the air may undergo oxidation and coincident changes similar to those just described as a result of shaking in air. But the rapidity and degree of change are not nearly so marked and a great deal that has been spoken and written about the dangers of allowing solutions of these arsenicals to stand before injection needs revision. Ehrlich and his collaborators laid great stress upon the necessity of injecting solutions immediately after their preparation, but we now know that undue haste is not required and that, indeed, in the case of solutions of arsphenamin, it is well to deliberately permit the solutions to stand for ten to twenty minutes in cylinders with the minimum exposure before injection since this results in a decrease of toxicity probably by a re-adjustment of physical factors.

In 1916, Schamberg, Raiziss and I showed that neutral solutions of arsphenamin may be kept in cylinders exposed to the air for four hours and usually for forty-eight hours before there occurred a demonstrable increase of toxicity for rabbits. When cylinders were filled to the stopper in order to exclude the air, toxicity was not increased for many days, even over periods of two to three weeks. On the other hand, in solutions kept in Erlenmeyer flasks and consequently with a greater surface exposed to the air, color changes and

increased toxicity occurred more rapidly than in solutions in cylinders with a much smaller surface of exposure.

Different lots of arsphenamin, however, behaved differently in these experiments, due no doubt to variations in the oxidizability of solutions or to variation in changes of physical factors concerned in toxic reactions. Sometimes solutions exposed for five days or longer, with marked color change and the formation of precipitates requiring an additional drop or two of alkali to effect their solution before intravenous injection, were less toxic than solutions standing but two or three hours—indeed, in some instances, less toxic than solutions injected immediately; these parodoxical results may have been due to oxidation to the point when the less toxic and less trypanocidal pentavalent compounds were produced.

Acid solutions of arsphenamin are more stable when exposed to the air than alkalinized solutions and undergo color changes and increased toxicity more slowly; neoarsphenamin and nepharsphenamin are quite susceptible to change. Color changes characterized by a gradual conversion of the usual light canary yellow solutions to greenish-yellow, green and finally blackish-green solutions are probably not due to the formation of "arsenoxid," which occurs as a white substance, but rather to oxidation of the amino-groups. Therefore, asolution may become toxic withuot coincident color change, as Roth observed with the solutions of some lots of deteriorated neoarsphenamins, but, as a general rule, a change in color to dark greenish-yellow indicates an increase of toxicity; clinically when a preserved solution of arsphenamin (Lowy) is found to have undergone such a change, it should not be employed.

Roth[31] has confirmed our observations that solutions of disodium arsphenamin may be kept in partly filled cylinders for at least five hours before an increase of toxicity for rats could be observed and more recently has pointed out that solutions allowed to stand for ten to twenty minutes are frequently less toxic for these animals than solutions injected at once. Hunt has likewise observed that solutions of some lots of arsphenamin kept in cylinders tend to lose in toxicity either within ten minutes after preparation or sometime within four hours, although different preparations varied greatly in this respect. Very probably this decrease in toxicity of arsphenamin solutions kept in cylinders with slight exposure to air is due to a decrease in the toxic physical factors without the coincident production of sufficient oxidized compounds to increase toxicity.

During the past year Dr. Schamberg and I, with the assistance of Miss Rule, have re-studied the influence of standing upon the toxicity of solutions of disodium arsphenamin in water and 5-per cent. glucose solutions and upon the toxicity of solutions of neoarsphenamin in water and glucose solution, the solutions being kept at ordinary room temperature in *Erlenmeyer flasks* with a large surface of exposure to the air. The maximum tolerated dose of each per kilo of weight was determined for rats of regulation weight by intravenous injection, with the following results:

	Disodium Arsphenamin in Water		Disodium Arsphenamin in Glucose Solution	
	Color	M.T.D.	Color	M.T.D.
Injected at once	No change	0.190	No change	0.200
Injected after 1 hour	No change	0.190	No change	0.200
Injected after 2 hours	No change	0.178	No change	0.200
Injected after 4 hours	No change	0.140	No change	0.200
Injected after 24 hours	Greenish-brown	0.120	Brownish	0.200
Injected after 72 hours	Black-green; ppt.	0.100	Brownish; no ppt.	0.160

	Neoarsphenamin in Water		Neoarsphenamin in Glucose Solution	
	Color	M.T.D.	Color	M.T.D.
Injected at once	No change	0.400	No change	0.400
Injected after 1 hour	No change	0.400	No change	0.400
Injected after 2 hours	No change	0.250	No change	0.250
Injected after 4 hours	No change	0.100	No change	0.100
Injected after 24 hours	Light green	0.100	Light-green	0.100
Injected after 72 hours	Brown-green	0.050	Brown-green	0.050

It will be observed that neoarsphenamin becomes toxic upon standing freely exposed to the air more rapidly than solutions of alkalinized arsphenamin and that solutions of disodium arsphenamin in 5-per cent. glucose undergo color changes and increased toxicity much more slowly than solutions in water; on the other hand, glucose solutions of neoarsphenamin behaved in very much the same manner as solutions in plain sterile distilled water.

From these experiments it would appear that solutions of disodium arsphenamin in water do not undergo appreciable increase in toxicity for at least an hour even when freely exposed to the air and in 5-per cent. glucose solution there is no increase in toxicity for at least four hours. On the other hand, as shown by Roth and Reid, there may be an actual decrease in toxicity after standing for ten to twenty minutes and this shows that the undue haste with which it is generally advised to prepare and inject solutions of arsphenamin in the treatment of syphilis is uncalled for and even unwarranted.

Solutions of neoarsphenamin, however, are less stable and glucose does not appear to protect this compound against color changes and an increase of toxicity as is the case with arsphenamin. For this reason this drug and sulpharsphenamin should be injected fairly promptly after solutions are made, although here again there are no reasons for undue haste as it would appear that an increase of toxicity does not occur during the first hour even when the solutions are freely exposed to air. According to the results of a few similar experiments which I have conducted with sulpharsphenamin, I believe that solutions of this compound in distilled water act in a manner similar to solutions of neoarsphenamin.

Not infrequently the question arises whether or not it is safe to keep solutions of arsphenamin, neoarsphenamin or sulpharsphenamin over a few hours or until the following day before administration. I believe that all may be safely kept for at least several hours *in narrow cylinders filled to the stoppers to prevent contact with air and* that, indeed, arsphenamin solutions may be kept in this manner for at least one or two days.

Influence of Alkalinization of Solutions of Arsphenamin, in Relation to Toxicity and Therapeutic Activity.—When commercial arsphenamin is dissolved in water or saline the solution is *acid;* when a solution of sodium hydroxid is slowly added, a heavy yellowish-white curdled precipitate is formed which dissolves upon the addition of more alkali and the addition of just enough to dissolve the precipitate to clear the solution (approximately 0.65 to 0.7 c.c. of a normal solution of NaOH per 0.1 gm. of compound) mainly forms a solution of the *monosodium* salt of arsphenamin. When about one-third more alkali is added to the clear solution totalling about 0.9 c.c. of normal NaOH solution a solution of the *disodium* salt of arsphenamin is produced.

Ehrlich found that *acid* solutions were very toxic for the lower animals when injected intravenously and likewise very painful for human beings when injected intramuscularly; he therefore warned against the use of such solutions and advocated adding to the solutions of arsphenamin, a 15-per cent. solution of sodium hydroxid, drop by drop, until the precipitate which formed was redissolved. An additional drop or two of the alkali was then added, which gave mainly a solution of the monosodium salt. Such solutions were shown to be relatively unstable in air, becoming turbid within a half hour in some cases and clinically, it was observed by others that solutions prepared by this method produced more reactions than those made more alkaline.

Experimental Observations on the Influence of Alkalinization upon the Toxicity of Arsphenamin.—The high toxicity of *acid solutions* of arsphenamin injected intravenously is

mainly due to the agglutination of erythrocytes and precipitation of blood proteins and the drug with the production of embolism and infarction described in Chapter XLV. In 1916 Schamberg, Raiziss and I showed that 0.5- to 1-per cent. solutions (equivalent to 0.6 gm. in 60 to 100 c.c.) injected intravenously in rabbits and rats were immediately toxic in doses of approximately 0.040 gm. per kilo, whereas neutralized or alkaline solutions were tolerated in doses of 0.090 to 0.100 gm. per kilo, showing that the acid solutions were 50 to 60 per cent. more toxic than the latter. Solutions of the *monosodium and disodium salts* of arsphenamin are, therefore, much less toxic than solutions of similar strength of acid solutions. Furthermore, *the disodium salt is somewhat less toxic than the monosodium salt.* For example, Danysz,[32] in 1917, concluded, on the basis of theoretical considerations and a number of experiments, that arsphenamin solutions made up with an excess of alkali were less toxic than those prepared in the usual manner. Roth[33] found that the intravenous injection of rats with 2 per cent. solutions of the monosodium salts of different lots of arsphenamin in dose of 0.1 gm. per kilo produced three to four times more deaths at the end of two and fourteen days than solutions of the disodium salts of the same compounds.

Several years ago I again studied this subject employing white rats injected intravenously at the rate of 1 c.c. per 2 minutes with 2 per cent. solutions of different brands of arsphenamin made up into three solutions as follows: (*a*) acid solutions; (*b*) solutions mainly of the monosodium salt containing just enough sodium hydroxid to dissolve the precipitates and (*c*) solutions mainly of the disodium salt containing 1 c.c. of normal sodium hydroxid for each 0.1 gm. of compound. Each solution was injected in increasing amounts and the following average figures show the largest doses per kilo of body weight proving immediately fatal and the largest amounts tolerated for 2 and 14 days respectively:

	Immediately Lethal	Maximum Tolerated Dose for 2 Days	Maximum Tolerated Dose for 14 Days
Acid solution	0.020 to 0.030	0.020	0.010 to 0.020
Monosodium solution	0.140 to 0.160	0.130 to 0.150	0.120 to 0.140
Disodium solution	0.160	0.140 to 0.150	0.110 to 0.130

These results show, in general terms, that 2-per cent. acid solutions of arsphenamin are six to eight times more toxic than neutral or slightly alkaline solutions; also that slightly alkaline solutions (disodium salt) are slightly less toxic in *two days* than neutral solutions (monosodium salt), but slightly more toxic than the latter at the end of fourteen days, confirming the observations of Lake,[34] who found that of rats injected with 0.100 gm. of arsphenamin per kilo in the form of 2-per cent. solutions neutralized with 0.75 c.c. of normal NaOH per 0.1 gm. of drug, 7.27 per cent. died in twenty-four to forty-eight hours and 5.45 per cent. after forty-eight hours, with 49.1 per cent. survivals; whereas, in a second group, injected with the same dose of the same compounds in 2-per cent. solutions alkalinized by the addition of 1.25 c.c. of normal NaOH per 0.1 gm. of drug, which was 30 per cent. in excess of the amount necessary to form the disodium salt, 3.84 per cent. died in twenty-four to forty-eight hours, 15.38 per cent. after forty-eight hours, with a survival of 44.23 per cent.

This brings up, therefore, the question of the *toxicity of hyperalkalinized solutions of arsphenamin.* Schamberg, Raiziss and I observed in experiments with rats, if one made up a solution of arsphenamin in 100 c.c. of water using just enough of a 15-per cent. solution of sodium hydroxid to neutralize the solution—that is, to the point of just dissolving the precipitate—that as much as 3 c.c. more of the alkali solution could be added to the clear solution without appreciably increasing its toxicity although the addition of 5 c.c. increased the toxicity in a definite manner. Lake has observed similar results upon the toxicity of sodium hydroxid alone for white rats by intravenous injection.

In this connection it may be mentioned that Roth has observed that the *quality of sodium hydroxid employed* may have a distinct influence on toxicity in white rats. He has lately encountered a so-called "chemically pure" sodium hydroxid, which, when made up as a normal solution, deposited, after standing several days, a considerable amount of a light brown gelatinous material. No chemical examination was made of this substance, but experiments on rats showed that solutions of arsphenamin alkalinized with the bottom portion of this sodium hydroxid solution containing the deposit was considerably more toxic (40 per cent. survivals for fourteen days) than a solution made alkaline with the top or clear portion (80 per cent. survivals for fourteen days).

Experimental Observations on the Influence of Alkalinization upon the Trypanocidal and Spirocheticidal Activity of Arsphenamin.—It is well established and quite clear, therefore, that neutral and slightly alkaline solutions

of arsphenamin are at least six to ten times less toxic than acid solutions. But how does alkalinization affect the toxicity of arsphenamin for parasites, that is, its therapeutic activity?

Ehrlich had observed that the acid solutions were distinctly more spirocheticidal (for *Sp. recurrentis*) than neutral solutions and I have observed that the same is true in regard to experimental trypanosome and *Spirocheta pallida* infections. White rats infected with *Tr. equiperdum* and injected intravenously twenty-four hours later with varying amounts of different brands of arsphenamin in 2-per cent. acid, neutral and alkaline solutions, as per the technic of my trypanocidal test, have shown the following average minimal curative doses per kilo of body weight:

Acid solutions	0.003 gm.
Neutral (mainly monosodium salt)	0.004 gm.
Alkaline (mainly disodium salt)	0.006 gm.

It will be observed, therefore, that acid solutions of arsphenamin are approximately *twice* as toxic for *Tr. equiperdum* as alkaline solutions and in a few experiments conducted with rabbits infected intratesticularly with *Sp. pallida* and treated after the development of lesions as described in Chapter XXI, essentially similar results were observed. But since alkalinization decreases toxicity for the host six to ten times, largely by reducing the acute intravascular hemoclastic reactions of agglutination, hemolysis and precipitation, no one has seriously considered the administration of acid solutions of arsphenamin even though the curative activity is at least twice that of equivalent amounts of arsphenamin in alkaline solution.

Clinical Observations on the Influence of Alkalinization of Solutions of Arsphenamin.—From the clinical standpoint, most interest centers upon the toxicity of solutions of arsphenamin alkalinized as described by Ehrlich just to the point of dissolving the precipitate and clearing the solutions as compared to those alkalinized by adding approximately one third more alkali than required for this purpose and with those rendered still more alkaline. Enough severe and even fatal reactions have resulted from the intravenous injection of acid solutions to preclude their clinical use.

Of course, it is not possible to express in figures the comparative toxicity of alkalinized solutions of arsphenamin for human beings as it is with the lower animals, but an analysis of available records in the literature shows that solutions of arsphenamin containing a slight excess of sodium hydroxid are less toxic for human beings than solutions prepared according to Ehrlich's method in which only one or two drops more of alkali are added after the solution has just cleared. For this reason Dr. McCoy, Director of the Hygienic Laboratory, has advised that each 0.1 gm. of arsphenamin be dissolved in a minimum of 20 c.c. of sterile distilled water or saline solution and neutralized with 0.9 c.c. of a normal solution of sodium hydroxid (approximately a 4-per cent. solution). However, most any strength of chemically pure sodium hydroxid from 4 to 15 per cent. may be employed if it is added to the solution in small graded amounts at a time, the physician recording in his mind the amount employed in drops or fractions of a cubic centimeter to just dissolve the precipitate and clear the solution and then adding arbitrarily one third more of this amount to the clear solution. This is probably a better method than adding the required amount of *normal* solution all at once, as 5.4 c.c. for 0.6 gm. of arsphenamin, unless one is sure that the normal solution is correct on the basis of titration. When one may rely upon the correctness of the normal solution it is permissible and perfectly good technic to arbitrarily add 0.9 to 1.0 c.c. for each 0.1 gm. of dissolved compound; otherwise, it is better to proceed as above described.

Solutions prepared in this manner do not become as quickly turbid upon standing exposed to the air and produce a lower incidence of toxic reactions. There is no advantage in adding more sodium hydroxid solution; toxicity is not reduced and the solution becomes more irritating to the veins producing

phlebitis and sometimes thrombosis. A great excess of alkali also increases the danger of intravascular reactions of hemolysis and agglutination.

Rate of Intravenous Injection of Arsphenamin and Its Substitutes in Relation to Toxicity.—As previously stated there is an intimate relation between concentration of solutions of arsphenamin and the rate of injection. In other words, a concentrated solution injected *slowly* may be as well borne as a dilute solution injected rapidly, but concentrated solutions injected rapidly certainly produce the highest incidence of toxic reactions in both man and the lower animals.

Roth has brought this out in a particularly clear and decisive manner in experiments employing guinea-pigs injected intravenously with 0.040 to 0.050 gm. of disodium arsphenamin per kilo in 2-per cent. solutions. When the dose was injected rapidly at the rate of 6 to 10 seconds, the mortality at the end of forty-eight hours was 57 per cent. and at the end of fourteen days, 67 per cent.; alternate animals injected slowly at the rate of 95 to 128 seconds, showed a mortality of only 7 per cent. at the end of forty-eight hours and 33 per cent. at the end of fourteen days. Similar results were observed with white rats injected with 0.100 gm. per kilo; among animals rapidly injected the mortality was 52 per cent. at the end of forty-eight hours and 56 per cent. at the end of two weeks in contrast with a mortality of 28 and 40 per cent. respectively among those slowly injected. From these experiments Roth concluded that the rate of administration is a potent factor in modifying the toxicity of arsphenamin, the toxicity increasing as the rate is increased. Furthermore, the depression of guinea-pigs and rats which occurs subsequent to the injection, was more pronounced after rapid than after slow injection.

Clinically, the difference between rapid and slow injections is less decisive, because the total amount of drug per kilo administered to human beings of average weight (0.6 gm. per 130 pounds) is approximately four to ten times less per body weight than employed by Roth in his experiments; but there can be no doubt of the fact that, in a broad and general manner, the rapid intravenous injection of human beings with solutions of disodium arsphenamin or silver arsphenamin, by using a large needle and gravity or by a syringe, produces more toxic reactions and especially more immediate or almost immediate reactions than slower injections requiring at least fifteen minutes for the injection of 100 c.c. or more of solution.

With solutions of neoarsphenamin, sulpharsphenamin and tryparsamid, the importance of rapid injection is much less because these compounds are very much less likely to produce acute intravascular reactions of hemolysis, agglutination and precipitation described in Chapter XLV. Even concentrated solutions of these as 0.45 to 0.9 gm. in 15 to 25 c.c. of water may be injected intravenously with a No. 22 needle at the rate of 1 or 2 minutes without increasing appreciably the incidence of toxic reactions in human beings, although I have found that both neoarsphenamin and sulpharsphenamin injected into white rats in the form of 4 per cent. solutions were distinctly better borne at the rate of 1 c.c. per two minutes than 4 c.c. per minute.

Toxic Reactions Caused by Rubber Tubing.—Of further interest in this subject of methods of administration of arsphenamin and its substitutes in relation to toxic reactions is the question raised by Stokes and Busman[35] of toxic reactions due to poisonous substances derived from rubber tubing employed in the gravity method of injection. These investigators studied the cause of an arsphenamin reaction, characterized by a chill with a sharp rise in temperature coming on from thirty minutes to one hour after intravenous injection, accompanied by nausea, vomiting, diarrhea, pain in the head and back and varying degrees of prostration. The reaction appeared in crops, so to speak, and then disappeared for a considerable period, only to recur in the midst of what appeared to be a period of flawless technical accuracy.

It was finally determined that this reaction resulted from the employment of a certain widely distributed brand of so-called pure gum rubber tubing.

The tubing, when new, appears to contain a toxic agent responsible for the reaction. The toxic substance gradually disappears from the tubing on use, and may be removed in the first instance by soaking it for six hours in normal sodium hydroxid solution and rinsing. The toxic property is not destroyed in the ordinary process of sterilization by boiling (from one-half to one hour), is not soluble in water or removable by irrigation, appears in toxic amounts in arsphenamin, neoarsphenamin and dilute sodium hydroxid solution merely on passing them through a new tube en route from container to vein, and apparently is not associated with the mechanically removable debris from the inner surface of the tube.

My friend, Dr. Walter I. Galland has discussed this interesting question at length[36] and ascribes the toxic effects largely to the presence of impurities. As stated by him "from the viewpoint of the rubber manufacturer it is possible to make rubber products free from any of the deleterious ingredients mentioned. These substances are not prerequisite to the compounding of superior rubber products, and such a product should be insisted upon. A tentative specification might be proposed in outline. Rubber goods intended for use within body cavities or in contact with body surfaces should be compounded of high grade new rubber, preferably para or plantation rubber. The use of reclaimed rubber, boiled or oxidized oils, or rubber substitute, should be prohibited. No filling ingredients containing lead, antimony, arsenic, chromium or other poisonous substance should be permitted."

CHAPTER XLIX

ROUTE OF ADMINISTRATION OF ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS IN RELATION TO TOXICITY AND THERAPEUTIC ACTIVITY

Shortly after the discovery of salvarsan and its introduction in the treatment of syphilis, the drug was administered by intramuscular injection. Solutions of the hydrochlorid in water (acid) produced so much pain and tissue necrosis that this method was abandoned in favor of intramuscular injections of alkaline solutions and Wechselmann's neutral suspension. Ehrlich observed from Hata's experiments with the lower animals that intramuscular injections gave a more continuous and intense therapeutic effect than intravenous injections although a great drawback to the routine use of the former route was the pain and disability produced. Attempts were then made to reduce the local reaction by injecting suspensions in oil and glycerin, but none of these methods served to appreciably reduce the considerable necrotic action and pain of arsphenamin and neoarsphenamin in full doses for the majority of adults.

The intravenous route, therefore, has become the usual and favorite one for the administration of arsphenamin and neoarsphenamin, not, however, because of superior therapeutic results, but primarily to render the injections free of pain and disability. Indeed, as will be shortly pointed out, the intramuscular route of administration appears to yield as good and even better therapeutic results than the intravenous route.

Arsphenamin and neoarsphenamin are also injected intraspinally and even intraventricularly for the treatment of some cases of syphilis of the central nervous system. They have also been given by mouth and by rectal injection. In some instances the powders have been applied locally to open syphilitic lesions and in this chapter it will be my purpose to discuss and compare these various routes of administration from the standpoints of toxic reactions and therapeutic results.

Intravenous Administration of Arsphenamin, Neoarsphenamin and Other Organic Arsenical Compounds in Relation to Toxicity and Therapeutic Activity.—In a broad and general manner it may be stated that intravenous injections of all of the organic arsenical compounds and especially of arsphenamin are more likely to produce toxic reactions than subcutaneous or intramuscular injections; this does not mean, however, that the latter routes are free of untoward effects aside from those of local pain and disability at the sites of injection. But in intravenous injections there are more chances of disturbing the physico-chemical equilibrium of the blood and producing toxic reactions by various physico-chemical reactions due to variations in viscosity, hydrogen-ion concentration, disturbances of acid-base equilibrium, the production of agglutination and hemolysis of erythrocytes, the formation of various precipitates, etc., already discussed with detail in Chapter XLV. Furthermore, rapid intravenous injections and especially of concentrated solutions, brings the drug in sudden contact with vital and important centers and organs and intensifies their physiological and pharmacological effects

so greatly that toxic effects may be produced. For example, the acute vasoparetic reaction or "nitritoid crisis" is usually produced by intravenous injections with sudden and immediate effects upon the vasomotor center and vasomotor nerves in hypersensitive individuals; intramuscular injections are very much less likely to produce this reaction because of slower absorption, although Milian[1] has recorded instances of "nitritoid crisis," "serous apoplexy" and acute vesicular eruptions from subcutaneous injections and regards this route of administration just as likely to produce toxic reactions as intravenous injections. Petges[2] also records the occurrence of acute reactions in 6 out of 57 patients treated with subcutaneous injections of sulfarsenol (sulpharsphenamin) although the reactions did not come on immediately as after intravenous injections, but rather several hours later which he considers an additional disadvantage, as the patient may be removed from observation and treatment.

It is true, however, that by attention to technical details in the administration of arsphenamin and neoarsphenamin the incidence of acute toxic reactions may be minimized, but the fact remains that they are more likely to occur than by intramuscular injections; *late* toxic reactions, however, as dermatitis and jaundice, are not as much influenced and, indeed, the incidence of dermatitis may be increased by accidental or purposeful subcutaneous injections.

From the standpoint of toxic reactions, the main disadvantage of intravenous injections is, therefore, the higher incidence of acute toxic reactions due to toxic physico-chemical factors of the drug, the sudden introduction of the drug, the toxicity of organic matter and other factors connected with the water or saline solution employed, etc. The main advantage is the freedom of pain and disability when intravenous injections are properly and skilfully given, and since all attempts to reduce the local necrotic effects of arsphenamin and neoarsphenamin in adult sized doses have not been generally successful, the intravenous route is to be preferred for the treatment of the majority of adults with these compounds, although small but adequate doses, and especially of neoarsphenamin, may be given to infants and young children in whom intravenous injections are difficult, impossible or dangerous (by the superior longitudinal sinus).

From the standpoint of therapeutic effects, the intravenous route is preferred in the acute early stages of syphilis for the rapid destruction of spirochetes in the lymph, blood and fixed tissues; but in the later stages, when the spirochetes are largely fixed in the tissues, the intramuscular or subcutaneous routes are to be preferred because absorption and elimination are reduced and spirocheticidal effects are actually improved probably by reason of the slower elimination which permits of the partial oxidation of larger amounts of arsphenamin and neoarsphenamin to the therapeutic oxids. At least, intramuscular or subcutaneous injections should be given from time to time alternately with intravenous injections for these more prolonged and continuous therapeutic results and it is very much desired, therefore, to have available an organic arsenical of the therapeutic activity of arsphenamin and neoarsphenamin but without the locally necrosing and painful effects of the latter by subcutaneous and intramuscular injection.

Subcutaneous and Intramuscular Injection of Arsphenamin, Neoarsphenamin, Sulpharsphenamin and Other Organic Arsenical Compounds in Relation to Toxicity and Therapeutic Activity. *Local Reactions Produced by Arsphenamin and Neoarsphenamin.*—From the standpoint of toxic reactions, the main advantage of subcutaneous and intravenous injections is the greater freedom from acute reactions, although it cannot be stated by any means that

acute and dangerous reactions are eliminated by these routes of administration. The main disadvantages are the local necrosing effects with resulting pain and disability, which may be quite considerable with the trivalent arsenicals as arsphenamin and neoarsphenamin, and various methods have been advocated for the subcutaneous and intramuscular injections of these compounds. Solutions of arsphenamin hydrochlorid in water (acid solutions) were among the first injected, but were quickly abandoned because of the very severe local reactions, in favor of Wechselmann's neutral suspension and alkaline solutions. Suspensions of arsphenamin were then advocated by Levy-Bing and Lafay,[3] Kromayer,[4] Pollitzer,[5] Hazen[6] and others, but abscesses and other severe reactions occurred, as reported by Hazen, by these injections as well as from suspensions of neoarsphenamin in glycerin advocated by Wolbarst.[7] More recently, however, some physicians of wide experience as Wechselmann,[8] Harrison, White and Mills,[9] Fordyce and Rosen[10] and others have developed methods for the subcutaneous and intramuscular injections of neoarsphenamin, which are said to produce local reactions not worse than the severe reactions produced by intramuscular injections of calomel and Sutton[11] has recently developed a method for intramuscular injections of arsphenamin. These methods will be described in Chapter LX, but here I may state that my experience with all of them has shown that most adults object to a series of injections if the doses are 0.3 gm. or over although a series of injections of smaller amounts of neoarsphenamin can usually be given to young children and infants with considerable success.

Local and General Reactions Produced by Sulpharsphenamin.—Within recent years, a new compound designated as sulfarsenol or sulpharsphenamin has been found to produce much less local reaction by subcutaneous or intramuscular injection. Preliminary reports by Levy-Bing and his associates,[12] Yernaux and Bernard,[13] Doble,[14] Crawford and Fleming[15] and others have indicated that this compound injected intramuscularly produces much less local irritation than either arsphenamin or neoarsphenamin; Emery and Morin[16] believe that subcutaneous injections are even better borne than intramuscular injections. However, according to Crawford and Fleming, the drug has not produced as good therapeutic results as arsphenamin in congenital syphilis; Durveux,[17] on the other hand, states that the serological results are jus as good and I will discuss this phase later with more detail.

My own experience with two brands of American made sulpharsphenamin have shown that this compound is generally better borne and especially by children, than either arsphenamin or neoarsphenamin and probably, better by subcutaneous than by intramuscular injection, although in some patients the reactions produced by subcutaneous and intramuscular injections of doses of 0.6 gm. dissolved in 2 to 5 c.c. of sterile water have been so severe that a series of injections could not be given. In other words, adult human beings in my experience vary greatly in their local reactions to this drug; in some individuals even small doses as 0.3 gm. have produced severe reactions while in others doses of 0.6 gm. were well borne although in no instance free of some reaction. The differences are not due altogether to the technic of injection, but to biological factors as well, and I have the impression that the local reactions are sometimes worse if large doses of the iodids are being given at the same time, as will be shortly discussed with more detail.

As previously stated, subcutaneous and intramuscular injections are not free of general toxic reactions similar to those produced by intravenous injections but developing later and more slowly. Dermatitis and jaundice may be produced as well as the more acute symptoms of nausea, vomiting,

diarrhea, etc., although the incidence of general reactions is lower than when these compounds are given intravenously.

Local Reactions Produced by Pentavalent Arsenical Compounds.—Pentavalent arsenicals as atoxyl, tryparsamid, amino-arsenophenol or "eparseno" (3:3′ diamino—4:4′ dioxy—arsenobenzene or Pomaret's "No. 132"), as a group produce less local reaction upon subcutaneous or intramuscular injection than the trivalent arsenicals. They are likewise less therapeutically active by both intravenous and intramuscular injection and must be given therefore in larger doses which usually results in local pain and some disability. Jeanseline, Pomaret and Bloch[18] have given as much as 0.12 gm. in 1 c.c. of Pomaret's amino-arsenophenol every other day for 25 consecutive injections by intramuscular injections high in the gluteal region.

Comparative Toxicity of the Organic Arsenical Compounds for the Lower Animals Administered by Intravenous, Intramuscular and Subcutaneous Injection.—While in human subjects arsphenamin, neoarsphenamin, sulpharsphenamin and other medicinal organic compounds of arsenic are less likely to produce general toxic reactions when given subcutaneously or intramuscularly than by intravenous injection, yet in the lower animals neoarsphenamin is more toxic by subcutaneous or intramuscular injection than by intravenous injection. This curious fact was first shown by Castelli[18] and confirmed by Schamberg, Raiziss and myself.[19] We observed that, while the highest average tolerated dose of neoarsphenamin for the rat by subcutaneous injection was 0.177 gm. per kilo, by intravenous injection it was 0.254 gm. per kilo. Arsphenamin, however, was always more toxic by intravenous than by intramuscular injection. It is difficult to explain this peculiarity of neoarsphenamin, unless it is due to the fact that when injected intravenously the drug is rapidly eliminated and therefore borne in higher doses than by subcutaneous or intramuscular injection when elimination is much slower although reduction by partial oxidation to the toxic oxids of the compounds in the tissues is much faster than occur with arsphenamin.

Sulfarsenol, or sulpharsphenamin, is likewise slightly less toxic by subcutaneous than by intravenous injection according to Voegtlin, Dyer and Johnson.[20] I have also found sulpharsphenamin slightly less toxic by subcutaneous injection, although the differences were not very great and frequently the maximal tolerated doses for rats were about identical.

Comparative Therapeutic Activity of Arsphenamin, Neoarsphenamin and Sulpharsphenamin by Intravenous, Intramuscular and Subcutaneous Injection.—Of almost equal interest and importance is the comparative therapeutic effects of the various medicinal compounds of arsenic by different routes of administration. When injected intravenously, elimination is ordinarily so rapid that one would expect a greater degree of therapeutic activity by subcutaneous or intramuscular injections of solutions of the compounds in a rapidly absorbable state and experiments with the lower animals have shown quite conclusively that with some compounds this is actually the case.

Castelli, for example, referred to above, found, in experiments with mice infected with *Sp. recurrentis*, that the smallest sterilizing dose of arsphenamin by both subcutaneous and intravenous injection was 0.0106 gm. per kilo, but the dose of neoarsphenamin by subcutaneous injection was 0.0166 gm. and by intravenous injection, 0.0199 gm. per kilo.

Voegthin and his associates have found sulpharsphenamin slightly more trypanocidal by subcutaneous than by intravenous injection and with arsphenamin and neoarsphenamin, Voegthin and Smith[21] state that the trypanocidal effects were as good after intramuscular as after intravenous injections.

My trypanocidal tests, conducted with rats infected with *Tr. equiperdum* and tested by Voegthin's method, have yielded similar results, not only with sulpharsphenamin but with neoarsphenamin and the disodium salt of arsphenamin as well, these results being summarized as follows and showing the smallest effective doses per kilogram of weight.

	Arsphenamin	Neoarsphenamin	Sulpharsphenamin
By intravenous injection.....	0.006 gm.	0.012 gm.	0.026 gm.
By intramuscular injection.....	0.004 gm.	0.008 gm.	0.018 gm.
By subcutaneous injection.....	0.004 gm.	0.008 gm.	0.022 gm.

It will be noted that intramuscular and subcutaneous injections of all three of these compounds yielded better trypanocidal effects than equivalent amounts injected intravenously; sometimes, and especially with sulpharsphenamin, slightly better results were observed after intramuscular than after subcutaneous injections. But it is also worthy of note that sulpharsphenamin is distinctly less trypanocidal than arsphenamin and neoarsphenamin; apparently those chemical alterations resulting in a decrease of its local toxic or organotropic effects also reduced its therapeutic activity.

Similar experiments employing rabbits injected with *Sp. pallida* have yielded somewhat similar results. In one of these tests the approximately smallest single doses of the three compounds per kilo of weight administered intravenously and intramuscularly, required to bring about a disappearance of the local scrotal lesions and sterilization of the lymphatic glands, were as follows:

	Arsphenamin	Neoarsphenamin	Sulpharsphenamin
By intravenous injection.....	0.014 gm.	0.018 gm.	0.030 gm.
By intramuscular injection.....	0.011 gm.	0.014 gm.	0.026 gm.

The discovery of a new arsenical compound more spirocheticidal than sulpharsphenamin but less irritating for the subcutaneous tissues and muscles, or at least, not more irritating, is very much needed for the treatment of syphilis and especially for chronic syphilis. Sulpharsphenamin is a great improvement over arsphenamin and neoarsphenamin for subcutaneous or intramuscular injection from the standpoint of local reactions, but is so inferior in curative activity that I believe it should not supersede either drug by intravenous injection except in those cases when intravenous injections cannot be given to obese adults or young children. Probably, the restrictions should not be as stringent as stated; in the treatment of chronic syphilis of adults to whom intravenous injections are very easy, it is frequently my plan to give a subcutaneous or intramuscular injection of sulpharsphenamin every third or fourth injection in order to prolong the effects and to permit the local tenderness to entirely subside before subsequent injections are given.

From the serological standpoint, intramuscular injections of arsphenamin have sometimes yielded better results than intravenous injections, alkaline solutions being employed in both, as reported by Craig;[22] Colonel Harrison states that in the British Army the serological results were better following intramuscular injections of neoarsphenamin than after intravenous injections.

Leonard[23] reports that in 511 patients treated with seven injections of neoarsphenamin and seven of mercury, the percentage of negative Wassermann reactions was higher after intramuscular than after intravenous injections and states that the former route of injection yielded excellent clinical results.

Stokes and others have reported satisfactory clinical results from subcutaneous and intramuscular injections of sulpharsphenamin. As for myself, it must be stated that in primary and secondary syphilis I have observed a more rapid disappearance of lesions and spirochetes from intravenous injections of 0.9 gm. neoarsphenamin than from intramuscular and subcutaneous injections of 0.4 to 0.6 gm. sulpharsphenamin. As stated by Tzanck and Dohen,[24] sulpharsphenamin by subcutaneous injection is valuable in the treatment of congenital syphilis and in patients with advanced and grave organic lesions, such as arteriosclerosis, aortitis or nephritis, but in the primary stage of syphilis and especially in the period of golden therapeutic opportunity before the Wassermann reaction has become positive, the intravenous route is always to be preferred; for myself, when intravenous therapy is indicated and especially in the treatment of acute early syphilis, I much prefer a good brand of neoarsphenamin, because the toxic effects are no greater and indeed usually less, while the therapeutic effects are much better.

Local Tissue Reactions Produced by Intramuscular Injections of Arsphenamin, Neoarsphenamin, and Sulpharsphenamin.—In conclusion, it may be well to briefly consider in a comparative manner the kind and degree of local tissue reactions produced by intramuscular injections of arsphenamin and its substitutes. It is well known, of course, that intramuscular injections of arsphenamin in neutral suspension, as originally employed by Wechselmann, in alkaline solution and suspended in oil, are more painful and produce larger and severer local reactions in human beings than intramuscular injections of similar doses of neoarsphenamin dissolved in an equal volume of water or suspended in the same amount of oil.

Swift[25] and others have shown in histological studies of the lesions excised from the lower animals that the difference in microscope appearance of the necrotic areas resulting from intramuscular arsphenamin and neoarsphenamin injections was quite striking. Following the arsphenamin injection, the necrosis and polymorphonuclear infiltration were most prominent, while following the neoarsphenamin injections the inflammation was of a chronic type, and the area was less sharply differentiated from the surrounding tissue.

I have endeavored to make a comparative study of the histological changes in guinea-pigs and rats produced by arsphenamin, neoarsphenamin and sulpharsphenamin, dissolved in water and suspended in oil, and injected intramuscularly. The amounts of drug injected have been mostly 0.025 gm. in 0.5 c.c. of menstrum for guinea-pigs; in some experiments employing rats the dose was 0.002 gm. in 0.2 c.c. of menstrum. The technical difficulties proved quite considerable from the standpoint of placing the study on a comparative basis, mainly because of the difficulties encountered in depositing the drugs in the same muscles in order to equalize as far as possible the effects of massage from the movements of the animals, as well as the subsequent removal of the lesions with sections through approximately the same places. Only by studying a large number of serial sections could one arrive at an approximate estimate of the comparative degrees of irritation produced. Sterile cotton seed oil was employed because I believe a vegetable oil is to be preferred to a mineral oil like paraffin oil, since saponification occurs in the tissues with better absorption and less chances of encapulation.

In the first place, intramuscular injections of sterile oil alone produces some histological changes characterized by slight degrees of muscle necrosis

and polymorphonuclear leucocytic infiltration; indeed, intramuscular injections of sterile distilled water alone have produced slight degrees of irritation and injections of alkaline water corresponding to the alkalinity of solutions of the disodium salt of arsphenamin, have produced considerable degrees of irritation characterized by muscle necrosis and leucocytic infiltration.

In a broad and general manner, the histological changes produced by all three of these arsenicals were quite similar, although varying in degree. All produce necrosis of muscle in contact with the deposited drug and all exert a positive chemotaxis upon polymorphonuclear leukocytes, although the leukocytes may not penetrate to the deposited drug and especially in the case of

FIG. 21.—LOCAL REACTION PRODUCED BY INTRAMUSCULAR INJECTION OF ARSPHENAMIN IN OIL.

Injection of 0.025 gm. of arsphenamin in 0.5 c.c. of sterile cotton-seed oil (5 days).

arsphenamin. Coagulation and liquefaction necrosis may occur and in lesions more than a week old before excision, evidences of fibrosis and encapsulation were evident. Sulpharsphenamin appeared to produce vascular necrosis with interstitial hemorrhages, more frequently than either arsphenamin or neoarsphenamin.

Figures 21 to 24 show in a general manner the comparative degrees of tissue injury produced by similar doses of these compounds. Solutions of the disodium salt of arsphenamin in water always produced more injury than solutions of neoarsphenamin and sulpharsphenamin in water. As

a general rule solutions of neoarsphenamin produced severer injury than solutions of sulpharsphenamin but this was not always the case. Indeed in many animals the sulpharsphenamin injury was slightly more severe than the neoarsphenamin injury, although human beings generally experience less discomfort and pain from intramuscular injections of the latter than from the former. Histologically, however, the degree of injury produced in guinea pigs and rats was frequently similar to that produced by neoarsphenamin and in several instances, the degree of vascular injury was more marked.

As a general rule suspensions of all three compounds in oil produced greater degrees of injury than solutions in water. I realize that this state-

Injection of 0.025 gm. of disodium arsphenamin in 0.5 c.c. sterile water (5 days).

ment is not in harmony with clinical experience, but nevertheless, the changes as observed showed that in suspensions in oil, the drugs themselves could usually be found in the tissues surrounded by greater degrees of muscle liquefaction and wider zones of leucocytic infiltration. It may be that the oil protects more against pain, but the size and severity of the local reaction was seldom less than observed with water solutions and sometimes greater. In other words, solutions of all three compounds in water produce more diffuse lesions probably because the drug is more rapidly diffused in the muscles; suspensions in oil produce more localized lesions, but since the

concentration of drug acting upon the muscle at the site of injection is greater, because diffusion is less, the degree of necrosis is usually greater with more evidences of liquefaction necrosis.

Influence of Iodids upon Intramuscular Reactions.—In a second series of experiments animals were given potassium iodid by mouth in dose of 0.02 gm. per kilo, corresponding to 1.2 gm. or 20 grains per 132 pounds, for six days before the drugs were injected intramuscularly. The resulting lesions frequently showed a greater degree of polymorphonuclear leucocyte infiltration and liquefaction necrosis than the animals not receiving iodid.

FIG. 23.—LOCAL REACTION PRODUCED BY INTRAMUSCULAR INJECTION OF NEOARSPHENAMIN IN OIL.

Injection of 0.025 gm. of neoarsphenamin in 0.5 c.c. sterile cotton-seed oil (5 days).

In conducting these experiments, smaller doses of the three compounds were injected in order to bring out more sharply the possible influence of the iodid administered. It is well known that intracutaneous injections of "luetin," agar, etc., produce larger and more pustular reactions in human beings under potassium iodid treatment than among those who have not taken this drug, as discussed with detail in Chapter LVII. These experiments indicate that intramuscular injections of the arsenicals in human beings taking potassium iodid may produce larger local reactions because iodin appears to favor suppuration, probably by increasing the activity of proteolytic enzymes derived from devitalized muscle and connective tissue cells

and leukocytes by inhibiting the influence of the antiferments, which, according to Jobling, Eggstein and Peterson, are apparently the unsaturated fatty acids of the body fluids. Similar experiments with intramuscular injections of various salts of mercury and potassium tartrobismuthate have yielded similar results as described in Chapters LIII and LV. I am not sure that, clinically, one may observe a greater degree of local reaction from intramuscular injections of various antisyphilitic drugs among individuals taking potassium or sodium iodid, because the injections are quite deep and differences in reaction may not become apparent, but these histological studies employing

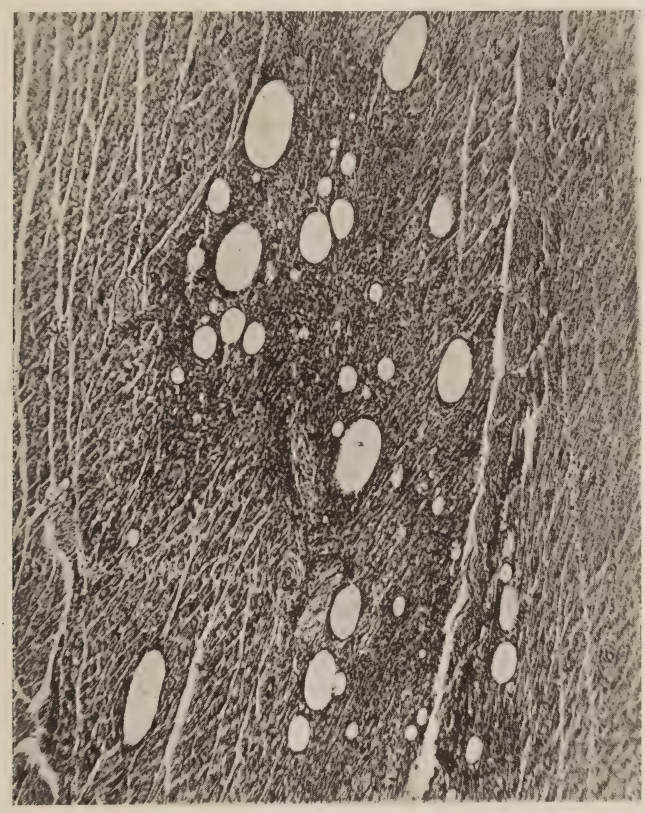

FIG. 24.—LOCAL REACTION PRODUCED BY INTRAMUSCULAR INJECTION OF SULPHARSPHENAMIN IN WATER.

Injection of 0.025 gm. of sulpharsphenamin in 0.5 c.c. of sterile water (5 days).

guinea-pigs and rats have shown that iodin tends to intensify the degree of local reaction.

Intraspinal, Intraperitoneal and Intrapleural Administration of Arsphenamin and Neoarsphenamin in Relation to Toxic Reactions and Therapeutic Activity.—When solutions of arsphenamin and neoarsphenamin are applied to open mucous membranes as those of the nose, mouth and pharynx, irritation is not ordinarily produced, but when injected intraspinally, even minute amounts are capable of eliciting rather sharp reactions in the pia and subarachanoid membranes. Intrapleural injections are likewise less well borne than intravenous injections, whereas intraperitoneal injections are

well borne as shown in the following results of my experiments employing rats and rabbits with particular reference to the average maximum tolerated doses of arsphenamin (disodium salt) and neoarsphenamin per kilo of body weight by these different routes of administration:

Route	Arsphenamin	Neoarsphenamin
Subcutaneous	0.250 gm.	0.150 gm.
Intravenous	0.120 gm.	0.250 gm.
Intraperitoneal	0.200 gm.	0.280 gm.
Intrapleural	0.080 gm.	0.080 gm.
Intraspinal	0.015 gm.	0.030 gm.

In comparison with the maximum tolerated doses by intravenous administration, it will be observed that by intraperitoneal injections the doses are appreciably greater, whereas by intrapleural injection they are about one third less and by intraspinal injection about one tenth less.

From the standpoint of therapeutic activity, the results of trypanocidal tests have been equally interesting and instructive. For example, in rats infected intraperitoneally with *Tr. equiperdum* by my method and treated twenty-four hours later, the smallest curative doses per kilo of body weight by these different routes of administration were as follows:

Route	Arsphenamin	Neoarsphenamin
Intravenous	0.005 gm.	0.012 gm.
Intraperitoneal	0.004 gm.	0.014 gm.
Intrapleural	0.007 gm.	0.016 gm.

The degree of tissue reaction as shown by the amount of congestion and serous and cellular reaction, is also greater in the subarachnoid and pleural spaces than in the peritoneal cavity, but doubtless irritation of important nerves and centers adds greatly to the low tolerance for both drugs injected intraspinally. Even though well diluted with spinal fluid, the intraspinal injection of human beings with amounts of arsphenamin in excess of 0.0005 gm. (½ mg.) or 0.002 gm. (2 mg.) of neoarsphenamin are likely to produce well-marked irritation and especially of the lower cord in the neighborhood of the site of injection, as shown by shooting pains in the legs and sometimes disturbances of both bladder and rectum. I have never seen in human subjects disturbances of the respiratory and cardiac centers, but such have been recorded in the literature and great care must be exercised in the intraspinal injection of these compounds. When administered the doses should seldom exceed 0.001 gm. (1 mg.) of arsphenamin and 0.002 gm. (2 mgs) of neoarsphenamin and one half these doses are the usual amounts; they should be well diluted with serum or saline solution and, finally and best of all, well diluted with 20 to 30 c.c. of the patient's own spinal fluid before slow administration by gravity injection.

I have discussed in Chapter LXXVI the therapeutic activity and indications for intraspinal therapy in neurosyphilis. The question is frequently raised whether the very minute amounts of arsphenamin carried over in 20 to 40 c.c. of serum, secured from blood drawn one half hour after the intra-

venous injection of 0.6 gm. of arsphenamin in the Swift-Ellis method, were sufficient for exerting spirocheticidal effects and whether the addition of 0.0005 gm. (½ mg.) of arsphenamin to 10 c.c. of serum in the Ogilvie method is sufficient for exerting spirocheticidal effects and especially when it is considered that both injections are still further diluted by at least 20 c.c. of spinal fluid. Studies *in vitro* summarized in Chapter XXVIII, show that arsphenamin and neoarsphenamin must be present in concentration of at least 1:1000 to destroy *Sp. pallida* and in the Ogilvie method the final dilution of 0.0005 gm. in 10 c.c. of serum and 20 c.c. of spinal fluid is at least 1:50,000, while in the Swift-Ellis method the dilution is still higher. Unquestionably, however, spirocheticidal activity *in vivo* is higher than *in vitro*, but it is almost certain that the minute amounts of arsphenamin and neoarsphenamin introduced into the spinal fluid by these methods are insufficient for exerting direct spirocheticidal effects; the therapeutic results are due to other changes. I know from the experiments summarized above with rabbits infected intraspinally with *Tr. equiperdum* that doses of these sizes are without appreciable trypanocidal effects. It is possible that some spirochetes on the surface of the meninges may be destroyed, but I very much doubt that organisms in the substance of the cord and brain are appreciably affected in intraspinal therapy by the drugs in the spinal fluid, although the resulting hyperemia and other changes induced in both meninges and substance of brain and cord may exert therapeutic effects, as discussed in Chapter LXXVI with more detail.

Intrapleural injections are without clinical significance or application, but intraperitoneal injections of neoarsphenamin may be of service in the treatment of infantile syphilis as indicated by recent case reports by Rosenberg and others and especially since there is an increasing tendency among pediatrists to give intraperitoneal injections of saline, blood, glucose, etc.

Oral and Rectal Administration of Arsphenamin and Neoarsphenamin in Relation to Toxicity and Therapeutic Activity.—As shown by Schamberg and myself the administration of arsphenamin by mouth exerts trypanocidal effects in rats and especially when the drug is given in solution or in capsules. The doses required for decisive effects, however, must be quite large as compared with intravenous injections. For example, the smallest trypanocidal dose of arsphenamin by intravenous injection of rats infected and treated according to the technic of my trypanocidal test, was about 0.005 gm. per kilo, but when the drug was given in solution by stomach tube at least 0.060 to 0.100 gm. per kilo were required, these amounts being, therefore, at least 15 to 25 times greater than required by intravenous injection. Rabbits given daily doses of arsphenamin equivalent approximately to 0.005 gm. per kilo or 0.3 gm. per 132 pounds for 29 to 31 days in succession showed no evidence of toxicity or histological changes in the internal organs; similar results were observed in experiments with dogs given pills and capsules of arsphenamin. Human subjects have been given 0.030 gm. (½ grain) of arsphenamin in capsules three times a day for many weeks without producing disturbing symptoms except mild digestive distress, and this is only a relatively small proportion of cases.

The oral administration of arsphenamin, therefore, exerts some curative activity as we have observed in the treatment of some cases of syphilis by this route of administration; untoward or toxic effects are seldom observed. Dr. Schamberg and I have never advocated the routine administration of the drug by this route, but we believe that it sometimes serves a useful purpose for the treatment of those patients who for various reasons cannot take the drug by intravenous infusion or intramuscular injection.

Within recent years many reports have appeared upon the rectal administration of arsphenamin and neoarsphenamin. Undoubtedly absorption occurs with therapeutic effects but only when very large amounts are given. With rats infected with *Tr. equiperdum* and treated twenty-four hours later by rectal injections, I found that the smallest curative dose was approximately 0.090 to 0.110 gm. per kilo for arsphenamin and 0.150 to 0.200 gm. per kilo for neoarsphenamin, these doses being therefore about 20 times greater than the smallest curative doses by intravenous injection.

Neoarsphenamin produces less irritation of the bowels than arsphenamin and when given in solution is the drug of choice; small doses in supppositories as 0.1 gm. of either are well borne when given every other day. Suspensions in a vegetable oil produce somewhat less irritation than solutions in water. Toxic effects as nausea and vomiting are of rare occurrence.

In the treatment of syphilis of individuals to whom intravenous injections cannot be readily given and who refuse intramuscular injections, as obese and nervous women or individuals who develop acute reactions, but to whom it is desired to administer arsphenamin or neoarsphenamin, rectal administrations are worthy of trial and it is easy to teach such individuals how to dissolve and administer neoarsphenamin to themselves since aseptic precautions are not required. Such indications, however, are exceptional and the cost of the large doses required is also prohibitive in many instances.

Local Application of Arsphenamin and Neoarsphenamin in Relation to Toxicity and Therapeutic Activity.—Unquestionably both arsphenamin and neoarsphenamin exert spirocheticidal effects when brought in contact with *Sp. pallida* and *Sp. pertenuis* in chancres, mucous patches and other syphilitic and frambesial ulcers, as well as upon other spirochetes, as in spirochetic gingivitis and Vincent's angina. Under the microscope final dilutions of arsphenamin with these secretions as high as 1:1000, destroy motility and kill the parasites as shown in cultural experiments. I have observed that 1-per cent. ointments of arsphenamin applied within one hour to inoculations of *Sp. pallida* to the scrotal skin of rabbits may prevent infection and the application of 1- to 4-per cent. solutions to the gums and pharynx undoubtedly exert curative effects in spirochetic gingivitis and Vincent's angina.

Solutions of both drugs and even the powders themselves applied to ulcers, the gums and pharynx are usually free of irritative effects probably on account of the secretions and character of the tissues. This is in sharp contrast with the irritation produced when solutions are injected into closed serous spaces as the subarachanoid, pleural and peritoneal cavities.

CHAPTER L

PROPHYLAXIS OF TOXIC REACTIONS PRODUCED BY ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS AND THE CONTRAINDICATIONS TO THEIR ADMINISTRATION

From the standpoint of the prophylaxis of toxic reactions following the administration of arsphenamin, neoarsphenamin and other remove organic compounds of arsenic, most interest is in relation to their intravenous injection, because this route is more likely to produce untoward effects than the subcutaneous and intramuscular routes. With the latter the chief object is to minimize the degree of local reaction of pain and disability, although general reactions and even the acute vasoparetic reaction, or "nitritoid crisis," may follow intramuscular and subcutaneous injections.

When arsphenamin or neoarsphenamin are injected intraspinally or intra-ventricularly, the chief concern is to minimize the degree of irritation of the meninges and the neighboring tissues; also to guard against excessive elevation of cerebrospinal fluid pressure. The various technical procedures to be employed for both of these purposes, as well as the reduction of pain and disability following subcutaneous and intramuscular injections, will be considered in Chapter LXII, devoted to the technic of administration of these compounds.

The question of the prophylaxis of toxic reactions following the oral and rectal administration of arsphenamin and neoarsphenamin hardly requires consideration, because these methods are not, or at least, should not be, employed except in very exceptional cases and nothing of special interest can be written of the prophylaxis of the reactions which they may produce as these effects are largely referable to direct irritation of the mucous membranes which subside as treatment is discontinued.

Our main interest in this chapter, therefore, refers to the prophylaxis of the general toxic reactions when the organic arsenicals are administered by intravenous, intramuscular and subcutaneous injection and especially in relation to intravenous injections, because with this route, we must deal with reactions due to the physical chemistry of solutions of the compounds and the acute changes that may occur in the blood stream as a result of the sudden introduction of solutions of the drugs, as well as the effects upon the fixed tissues. With subcutaneous and intramuscular injections, absorption is much slower and the incidence of toxic reactions (aside from local pain and disability) much less.

General Measures for the Prophylaxis of Toxic Reactions.—Since toxic reactions may be due primarily to the drug, to the patient or to the method

of administration as summarized in Chapter XLIV, so may the various prophylactic measures be grouped under the same three divisions as follows:

1. Referable to the Drug
   - (1) Avoid stale products (over 2 years since manufacture).
   - (2) Do not use drugs in cracked ampules.
   - (3) Do not use drugs of changed color or with strong odor.
   - (4) Do not use difficultly soluble neoarsphenamin.
   - (5) Do not inject any solution unless perfectly clear.
   - (6) Examine labels carefully to prevent the administration of arsphenamin in mistake for neoarsphenamin or sulpharsphenamin.

2. Referable to the Preparation and Administration of Solutions
   - (1) Use only freshly distilled sterile water or saline free of organic matter, or distilled water hermetically sealed against contamination.
   - (2) For dilute solutions (50 c.c. or more) use saline in preference to water.
   - (3) Avoid hot water for neoarsphenamin and sulpharsphenamin.
   - (4) Dissolve drug with minimum of shaking.
   - (5) For arsphenamin use preferably 20 to 30 c.c. of solution for each 0.1 gm. of drug.
   - (6) For arsphenamin use ⅓ excess of sodium hydroxid or 0.9 c.c. of a *normal* solution for each 0.1 gm.
   - (7) Filter all solutions.
   - (8) Allow solutions of arsphenamin to stand 10 to 20 minutes before injection.
   - (9) Inject slowly using at least 2 minutes for each 0.1 gm. of arsphenamin injected in dilute solution by gravity. For concentrated solutions of neoarsphenamin and sulpharsphenamin (15 c.c.) use at least one half minute for each 0.2 gm. of drug.
   - (10) For gravity administration avoid new rubber tubing unless previously prepared.

3. Referable to the Patient
   - (1) Allay fear and nervousness.
   - (2) Avoid undue haste; avoid operating rooms and a display of instruments, etc.
   - (3) Releave constipation.
   - (4) Inject one to several hours after last meal.
   - (5) Avoid injection during menstrual period.
   - (6) Give preliminary attention to the condition of the teeth, tonsils and other possible foci of infection.
   - (7) Examine urine for the condition of the kidneys and especially if mercury or bismuth have been given.
   - (8) Estimate functional capacity of liver in selected cases.
   - (9) Give but ½ to ¼ usual amount for first dose.
   - (10) In chronic syphilis start treatment with mercury, bismuth or with small doses of the arsenicals to prevent Herxheimer reactions.
   - (11) Exercise special care in cases of pregnancy as severe reactions may produce abortion or miscarriage.
   - (12) When administering pentavalent compounds as atoxyl or tryparsamid, have the vision and eye grounds examined repeatedly to guard against toxic amblyopias.
   - (13) Give intramuscular injections deep in the muscles; avoid injections in fatty tissues and in the neighborhood of large nerves.
   - (14) Give patients likely to develop acute vasoparetic reactions $\frac{1}{50}$th grain of atropin alone or in conjunction with a small injection of the drug ($\frac{1}{10}$th the dose) about one hour before the main injection.

All except the last mentioned of these factors have been discussed in preceding chapters and need not here receive further attention. *Since arsphenamin tends to produce more reactions than either neoarsphenamin or sulpharsphenamin, the subject of prophylaxis is of special interest in relation to the administration of this compound* and, as previously stated, the subject is

of more importance in relation to intravenous than intramuscular and subcutaneous injections.

Special Measures for the Prophylaxis of Acute Toxic Reactions.—Various additional measures have been proposed for the prophylaxis of acute reactions following intravenous injections of arsphenamin or neoarsphenamin and especially the former for the purpose of permitting the treatment of those exceptional cases of syphilis peculiarly hypersensitive to these drugs and likely to develop acute reactions on the table or immediately after injection.

I have already discussed in Chapter XLVI the injection of arsphenamin and neoarsphenamin in sterile glucose solution for this purpose. Glucose evidently delays or prevents the reduction and oxidation of the compounds and lowers especially the toxicity of arsphenamin. I have commonly employed a sterile isotonic 5-per cent. solution of chemicals pure glucose in distilled water for the administration of arsphenamin and concentrated solution (0.4 gm. in 25 c.c.) and believe that it aids in preventing untoward effects. Pranter,[1] Steinberg,[2] Dulrot,[3] Cheinisse[4] and others abroad, however, have recommended the use of hypertonic solutions (10- to 50-per cent.) with apparent success. As a general rule, about 30 c.c. of 20- to 30-per cent. solutions of Merck's glucose in distilled water have been employed and Steinberg states that the spirocheticidal effects are increased in addition to a reduction in toxicity. I doubt the correctness of this observation and rather suspect that carefully controlled experiments would show a reduction in therapeutic activity by solutions of these concentrations. Cheinisse states that glucose solutions also reduce the incidence of arsenical dematitis and jaundice and their use is worthy of serious consideration for the administration of arsphenamin and its substitutes to difficult patients, that is, individuals who have shown signs of a high degree of intolerance for these compounds.

An excellent drug for preventing the acute vasoparetic reaction is adrenalin in dose of 2 to 8 minims of 1:1000 solution by subcutaneous injection just before or during the injection of arsphenamin as advocated by Berman[5] and others. But great care must be exercised, as otherwise a vascular shock may be produced almost as dangerous as the arsenical reaction itself, as observed Stokes. Adrenalin however, is our most valuable remedy for the treatment of the acute vasoparetic reaction ("nitritoid crisis") and I believe should be reserved for this purpose rather than administered prophylactically.

Stokes[6] and Busman[7] have advised the subcutaneous injection of $\frac{1}{50}$th grain of atropin sulphate about 20 minutes before the injection of arsphenamin. Smaller doses have proven ineffective for adult cases. In their experience atropin has controlled the immediate reactions and permitted a continuation of arsenical treatment of a number of cases. I have used the drug in the type of cases described by Stokes and Busman with success and believe that it is a good plan to inject $\frac{1}{50}$th grain before the injection of arsphenamin or neoarsphenamin whenever an acute reaction is feared and to have 0.5 c.c. of 1:1000 adrenalin ready for injection if the atropin fails to check the arsenical reaction.

Tzanck and Radot[10] advise giving 0.1 gm. of neoarsphenamin by mouth one-half, one or even twenty-four hours before intravenous injection as a means of prophylaxis; I have had no experience with this method. Kenedy[11] advises administering neoarsphenamin dissolved in 10 c.c. of a 10-per cent. solution of calcium chlorid in water but my experience with this method has been bad owing to the toxic reactions sometimes produced by calcium. Sicard has advised the preliminary intravenous injection of 30 c.c. of saline containing 0.6 to 0.75 gm. of sodium carbonate on the basis of the Danysz

theory that the acute reactions are due to changes in the inorganic constituents of the blood. This method, however, has not proven successful in the experience of others.

The Prophylactic Effects of a Small Preliminary Injection of the Arsenical Compound.—Of special interest in connection with this subject of the prophylaxis of the acute immediate arsenical reactions are the effects of a small preliminary intravenous injection of the drug for the purpose of "desensitizing" the patient in a manner analogous to the subcutaneous injection of 1 c.c. of horse serum one hour before the intravenous injection of antipneumococcus or other immune serum. Danysz[12] has mentioned this subject several years ago in connection with his experimental work and more recently Kolle[13] has stated that preliminary "vaccination" injections reduce the toxicity of arsphenamin for the lower animals. Stokes and Busman, previously referred to, have likewise found the method of use clinically either alone or in combination with the subcutaneous injection of $\frac{1}{50}$th grain of atropin and Busman has employed preliminary intravenous injections of $\frac{1}{10}$th the prescribed dose one hour before the main injections, with apparent success in a series of cases.

It is very difficult to evaluate these various prophylactic methods by experiments with the lower animals, because they apparently do not develop acute reactions similar to the "nitritoid crisis" of human beings, although it is well known that rats vary in susceptibility to the arsenical compounds. But in several experiments I have observed that the preliminary or "vaccinating" injections of arsphenamin and neoarsphenamin have apparently increased the tolerance of rats for these compounds administered by the usual method described in Chapter II, as shown in the following summary. In other experiments no influence upon toxicity was apparent and the results were usually more definite with arsphenamin than with neoarsphenamin:

(*a*) The maximum tolerated dose of a solution of the disodium salt of a lot of arsphenamin was between 0.100 and 0.110 gm. per kilo; when administered one to five minutes after the preliminary intravenous injection of 0.001 gm. per kilo the maximum tolerated dose was raised to 0.140 to 0.150 gm. per kilo.

(*b*) The preliminary injection of 0.005 gm. of a lot of disodium arsphenamin one minute before raised the maximum tolerance from about 0.100 gm. per kilo to about 0.130 gm. and given one hour before, raised the tolerance to about 0.140 gm. per kilo.

(*c*) The maximum tolerated dose of a solution of the disodium salt of a lot of arsphenamin was 0.130 gm. per kilo; when administered twenty four hours after the preliminary intravenous injection of 0.005 gm. per kilo the maximum tolerated dose was more than 0.150 gm. per kilo. With another toxic lot of arsphenamin borne only in dose of 0.090 gm. per kilo, the preliminary injection of 0.005 gm. per kilo twenty-four hours before raised the tolerance to 0.100 gm. per kilo. With a second toxic lot borne only in dose of 0.090 gm. per kilo, the preliminary injection of 0.005 gm. per kilo twenty-four hours before raised the tolerance to 0.120 gm. per kilo.

(*d*) With neoarsphenamin the results were not as definite and in most experiments, the preliminary injections did not increase the tolerance; indeed, the reverse was frequently noted due, in part, to excessive hemorrhages, since neoarsphenamin especially increases the bleeding time. In one experiment, however, the preliminary injection of 0.005 gm. of neoarsphenamin per kilo one minute and one hour before apparently raised the tolerance for a particular lot from 0.280 gm. to 0.320 gm. per kilo.

It would appear, therefore, that the preliminary injection of a small dose of arsphenamin or neoarsphenamin may materially increases tolerance for these drugs and especially for arsphenamin. The method doubtless possesses practical clinical value as shown by Danysz, Stokes and Busman, but it is to be borne in mind that the use of preliminary injections of atropin, adrenalin or of the drug or of a combination of $\frac{1}{10}$th of the dose of drug intravenously and $\frac{1}{50}$th grain of atropin subcutaneously about one hour before the main injection, are only indicated for those occasional individuals who are hypersensitive to the drugs and likely to develop the immediate vasoparetic reaction. These methods are not particularly advised for the prophylaxis of the gastro-intestinal, protein shock or late reaction as dermatitis and

jaundice, although they may be indicated in cases of several gastro-intestinal reactors since these are to be interpreted as acute vasoparetic reactions of the gastro-intestinal mucosa.

Contra-indications to the Administration of Arsphenamin, Neoarsphenamin and Other Organic Arsenical Compounds.—This naturally brings up for consideration the question of the contraindications to the administration of the organic arsenical compounds in the treatment of syphilis and other diseases. Rather formidable lists of various acute and chronic diseases have been published by different writers, but as our knowledge of the pharmacology and toxicology of arsphenamin and its substitutes has advanced the list of contraindications has diminished. Furthermore, while one drug of the group, as arsphenamin, for example, may be contraindicated in any given individual, another as neoarsphenamin or sulpharsphenamin, may be given with safety.

Probably the only real contraindication to these drugs as a group is *hypersensitiveness to arsenic.* Individuals developing acute reactions, dermatitis and allied lesions, jaundice, etc., are always bad risks and usually demand that treatment shall be continued with other antisyphilitic drugs as mercury and bismuth. It is sometimes possible, as in cases developing minor *dermatoses,* to continue arsenical treatment with another kind of compound beginning with small doses, gradually increased, but with a sharp lookout for urticaria, fleeting erythemas, itching of the palms and soles, paresthesia, etc. Sometimes individuals developing acute reactions after intravenous injections of arsphenamin or neoarsphenamin can stand small, ascending doses of sulpharsphenamin by subcutaneous or intramuscular injections; cases of dermatitis due to sulpharsphenamin may sometimes bear intravenous injections of neoarsphenamin, but I repeat, on the bases of experience, that extraordinary caution is required when arsenical treatment is resumed after the subsidence of any of the different arsenical dermatoses described in Chapter LI.

Cases of *jaundice* are always bad risks unless they are due to syphilitic hepatitis when just the reverse is true, But if jaundice has been produced by the previous injection of arsenical compounds, there are risks of its recurrence from the administration of any of the organic arsenicals although arsphenamin is probably better borne by these cases than neoarsphenamin. Likewise in cases of jaundice due to infection of the gall-bladder and ducts it is possible for functional activity to be so reduced as to lower the tolerance of the organ for arsenic and due caution must be exercised with preference for small doses in order to avoid too sudden accumulation of arsenic with possible histological changes of cloudy swelling and fatty degeneration.

Conditions of these kinds, may, therefore, absolutely forbid the administration of arsenic in any form. It is true that very small doses may be given even under such circumstances, but the question then arises whether they would be worth while from the standpoint of therapeutic results. In a broad and general manner, I think it may be stated that, whenever doses of 0.1 to 0.2 gm. are contra-indicated, it is better to abandon arsenical treatment and employ mercury or potassium tartrobismuthate in conjunction with the iodids. This is especially true in the presence of acute syphilitic lesions; it is not necessarily true, however, in chronic syphilis since doses of 0.1 gm. of arsphenamin or neoarsphenamin or even less over long periods of time sometimes result in surprisingly good results and especially in chronic cardiovascular syphilis.

Arsphenamin is sometimes contra-indicated in *grave cardiovascular disease* with high blood-pressure, because of the dangers attending a sudden increase

of blood-pressure due to the drug, the injection of 200 c.c. or more of solution, fear, or a combination of these. In advanced syphilitic aortitis and myocarditis and especially if meningovascular syphilis is suspected or known to be present, preference should be given to those arsenicals like neoarsphenamin or sulpharsphenamin, that may be given in concentrated solution with a syringe with the minimum of excitement. Cases of syphilis with intracerebral hemorrhage (apoplexy) especially require great care although small (0.2 gm. or less) doses of neoarsphenamin may be given with safety insofar as increasing blood-pressure is concerned. The same is true in case of *tuberculosis with hemoptysis;* the arsenicals are not actually contra-indicated, but due care must be exercised in their administration with special reference to the use of small doses of those drugs like neoarsphenamin, that may be given in concentrated solutions with least chances of suddenly increasing blood pressure. Objection may be raised to neoarsphenamin because it tends to lower the coagulation and bleeding time of the blood, but in human beings these effects are not noted with the doses ordinarily employed.

Other diseases as *advanced diabetes and non-syphilitic nephritis* are usually mentioned as contraindications. This may be true insofar as full sized doses are concerned, but not with smaller doses if hypersensitiveness to arsenic is absent. Diabetes mellitus is not itself a syphilitic disease although the diabetic may have syphilis in addition and the latter may require treatment. Doubtless, the tolerance of advanced cases is much lower than among non-diabetic individuals, but the difficulty is usually solved by the administration of neoarsphenamin in doses of 0.2 to 0.6 gm. Advanced nephritis is of course a grave danger because of the possibility of interference with the elimination of arsenic. Syphilitic nephritis usually improves rapidly under arsenical treatment and I have observed the rapid disappearance of albumin and casts in the urine in cases of non-syphilitic nephritis under neoarsphenamin treatment. Certainly arsphenamin or neoarsphenamin is to be preferred to either mercury or bismuth and, if treatment must be given in spite of the nephritis, I believe that intravenous injections of neoarsphenamin in dose of 0.2 to 0.4 gm. once a week or intramuscular injections of the same amounts of sulpharsphenamin are the remedies of choice.

It is sometimes stated that the arsenicals should not be given to persons of *advanced years*. Age as such is not an absolute contra-indication, but the possibility of stirring up latent syphilitic infection in the nature of Herxheimer reactions may be worthy of very serious consideration. When chronic latent syphilis is discovered in the aged, it is sometimes better to leave the disease untreated; acquired acute syphilis of the aged of course requires treatment. At all events, the kidneys and liver of those over 65 years of age are not apt to be as functionally active as in younger years and our method of treating individuals of this age or older should be along less energetic lines than is possible with younger persons. Arsphenamin and its substitutes, therefore, are not necessarily contra-indicated in those of advanced years; only full-sized doses and intensive methods of treatment may be contra-indicated with these compounds as is likewise true of mercury and bismuth. Furthermore, clinical judgement must be exercised in deciding whether or not treatment is indicated at all. It is sometimes a matter of wisdom not to treat cases of chronic latent syphilis, although in the presence of chronic active syphilis with progression of lesions and symptoms enough treatment must be usually given to hold the disease in check. But, whenever treatment is given, it should begin mildly and with small doses to minimize the danger of Herxheimer reactions and especially if the nervous system is involved.

In *syphilis of the optic nerve* or other portions of the eye, pentavalent arsenicals as atoxyl and tryparsamid may be contra-indicated, because of the well-known tendency of these compounds to produce toxic amblyopias. The trivalent compounds as arsphenamin, neoarsphenamin and sulpharsphenamin, however, may be given but always in small, ascending doses in order not to produce Herxheimer reactions. The same is true in syphilis of other of the cranial nerves and especially the auditory and oculomotor nerves in order to guard against the production of neural Herxheimer reactions (neuro-recidives).

In severe endocrine disturbances and especially of the thyroid and adrenal glands, the arsenicals should not be given or if so, in small, guarded doses. Likewise in *pregnancy*, the arsenicals should be administered with all precautions against severe reactions because of the danger of producing abortion or miscarriage; my own preference is for neoarsphenamin. It need scarcely be stated that in *acute infectious diseases* or immediately thereafter, tolerance for these compounds may be reduced indicating smaller doses than usual although the arsenicals are not absolutely contraindicated.

As previously stated, therefore, the only absolute contra-indication to the administration of arsphenamin and its substitutes is hypersensitiveness to these compounds rendering dangerous or impossible the administration of even small doses. Fortunately, the number of such cases is indeed very small. On the other hand there are some diseases in which the doses of the various arsenicals by intravenous injection must be reduced or preference given subcutaneous or intramuscular injections of sulpharsphenamin in the interests of safety and in which one kind of arsenical may be less dangerous and to be preferred to others.

CHAPTER LI

ETIOLOGY, SYMPTOMS AND TREATMENT OF TOXIC REACTIONS FOLLOWING THE ADMINISTRATION OF ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

Having thus reviewed in the preceding chapters the general physico-chemical and chemical causes of toxic reactions produced by the administration of some of the medicinal organic arsenical compounds, as well as those reactions more properly ascribed to pathological conditions of individual

patients or to methods of administration and the prevention of these reactions as based upon our present knowledge of these many and diverse causes, we may now consider from the standpoint of clinical manifestations and treatment the different symptom-complexes and lesions and especially those sometimes produced by the intravenous injection of arsphenamin, neoarsphenamin and sulpharsphenamin. From the etiological standpoint the subject is still quite obscure and in most instances the toxic reactions cannot be ascribed exclusively to a single sharply defined agent, but are due rather to a combination of causes in which one, perhaps, may stand out with particular prominence and importance.

Usual Effects Produced by the Administration of Arsphenamin and Its Substitutes.—However, before discussing the toxicological reactions sometimes produced by the *intravenous* injection of arsphenamin and its substitutes a few words are required concerning what may be called the normal or physiological effects, because minor and unimportant reactions occur with some individuals which cannot properly be designated as truly toxicological. Furthermore, some patients are very nervous and dread the injections which alone may be responsible for signs and symptoms of syncope and nausea without in any way incriminating the drug or method of administration as reported by Bender[1] and others; indeed, such symptoms may develop with the introduction of the needle and before any drug has been injected at all due entirely to fear and nervousness and especially if much pain has been produced.

Furthermore, it is to be emphasized that in the great majority of cases the intravenous injection of neoarsphenamin and supharsphenamin by technically correct methods is not followed by any untoward effects whatsoever; arsphenamin is more likely to produce minor disturbances due to the greater variation in physicochemical properties as well as to the injection of larger volumes of fluid, but since 1920 the incidence of toxic reactions produced by arsphenamin and neoarsphenamin has certainly decreased in comparison with the incidence of reactions in preceding years.

Probably the first effect to be mentioned by the patient is a peculiar *odor* and *metallic taste,* usually resembling ether; this very commonly happens after the intravenous injection of the first few cubic centimeters of solutions of arsphenamin and neoarsphenamin and in no way indicates a toxicological reaction of the approach of such. Evidently this effect is due to a circulation of the drug through the nose, mouth and accessory glands with rapid elimination and indicates the extremely rapid diffusion of these drugs administered by intravenous injection. It is my custom to advise patients to chew a chiclet or some other highly flavored gum for fifteen minutes during and after the injection, which aids in disguising the ether taste.

Not infrequently patients experience a *feeling of fullness* in the head and show slight *flushing of the face* which last for only a few minutes or indeed seconds, due to the physiological effects of arsphenamin upon the vasomotor system, and, in the case of arsphenamin, to the increase of blood-pressure and the injection of 100 c.c. or more of fluid. These effects may also occur after the injection of neoarsphenamin and sulpharsphenamin, but only occasionally and in exceptional cases, since these compounds do not affect the vasomotor system to the same degree as arsphenamin and are usually administered in concentrated solutions. The physician may note the flushing followed by slight *perspiration,* without any complaint from the patient. Sometimes these fleeting effects are followed by a slight feeling of *faintness* which quickly passes off, to be followed by a sense of elation that the ordeal of injection is over. Sometimes nausea and even vomiting occur

and especially if the patient is nervous and has eaten within half an hour of the time of injection, but these effects quickly pass away and are due primarily to the ether taste which is especially disagreeable to patients who have taken ether for anesthetic purposes on former occasions.

In some cases of chronic latent syphilis the first injection or two of arsphenamin or neoarsphenamin is followed within a day or two by malaise, some loss of appetite and vague pains in the heart, lymph-glands and muscles. I have interpreted these pains as due to the provocation of latent areas of syphilitic infection which are not in a strict sense the results of toxicological effects of the drugs and which have been discussed in Chapter XLVIII with more detail.

Intramuscular and subcutaneous injections of sulpharsphenamin usually produce brief burning and stinging pain but rarely nausea and vomiting. I have already discussed these local effects in Chapter XLIX; here it may be emphasized, however, that children as a rule complain much less than adults and adults vary greatly in their reactions to intramuscular injections. Some refuse injections by this route after the first on account of the pain and disability produced and this is not always due to imagination or nervousness but to a reduced state of general nutrition and resistance which results in excessive local reactions.

Acute Physico-hemoclastic Reaction, with Special Reference to That Produced by Acid Solutions of Arsphenamin.—*Etiology.*—Under this heading I refer to the acute and frequently fatal reactions caused by the intravenous injection of solutions of arsphenamin in water without neutralization (acid solutions); as stated in Chapter XLV, the injection of such solutions and particularly the rapid injection of concentrated solutions, may produce profound intravascular reactions of agglutination, hemolysis and precipitation with severe and sometimes fatal effects. I have known of several fatalities of this kind due to errors on the part of physicians injecting concentrated solutions of arsphenamin in mistake for neoarsphenamin and sulpharsphenamin. If acid solutions of arsphenamin are well diluted as 0.4 to 0.6 gm. dissolved in 200 to 300 c.c. of water, and slowly injected, the patient may escape a severe reaction and, indeed, not a few individuals owe their lives to these fortuitous circumstances.

Severe reactions of this kind due primarily to acute physical intravascular reactions have also been caused by solutions of arsphenamin to which too much sodium hydroxid has been added; also by solutions to which sodium hydroxid has been added followed by the addition of an excess of hydrochloric acid when the physician has been in doubt regarding the end reaction and fitness of the solution. Whether or not the acute immediate reactions produced by the intravenous injections of properly neutralized (monosodium salt) or slightly alkalinized (disodium salt) solutions of arsphenamin and cloudy solutions of neoarsphenamin are to be placed in this category, cannot be stated. Doubtless they are in part due to physicochemical phenomena as changes in the viscosity, solubility, etc., of the solutions and in some cases it is possible that intravascular agglutination and precipitation may occur; but as stated in Chapter XLV, the plasma affords a great degree of protection against these changes when ordinary doses are given whereas with the rapid injection of acid solutions of arsphenamin this protection is generally insufficient. In other words, intravascular reactions may play a part in the production of the "nitritoid crisis" or acute vasoparetic reaction shortly to be discussed, but under the present heading I include those reactions in which intravascular physical changes of hemolysis, agglutination and precipitation are primarily or solely responsible for the toxic effects and especially

those due to errors in administration, as the intravenous injection of concentrated acid or over alkalinized solutions of arsphenamin.

Symptoms.—The symptoms develop almost immediately and are mainly due to widespread embolism and infarction, especially of the lungs, with secondary cardiac dilatation. The patient expresses a fear of approaching death, presents an anxious and appealing expression, develops hiccough or short spasmodic cough and complains of severe pain in the thorax and especially a sense of constriction and suffocation. The pulse is rapid and at first full and bounding followed by irregularity and extreme weakness; coma generally follows from cerebral anemia, although convulsions may be present apparently due to cerebral embolism involving motor areas. In not a few cases death has followed immediately or within an hour or two or the patient partially recovers to succumb during the following twenty-four hours. In less severe cases when the injections have been interrupted in time, recovery from the acute reaction has occurred followed by the development of bronchopneumonia due to embolism. In not a few instances the physician has discovered his error of failure to neutralize or alkalinize the solution almost immediately after infusion of the solution has been started and immediate interruption of the injection has been followed by no untoward effects from the injection of a few cubic centimeters; under such circumstances there is nothing to fear, toxic reactions are not likely to develop and treatment is unnecessary except possibly the intramuscular injection of atropin to stimulate the heart.

Treatment.—The first step in treatment is, of course, to interrupt the injection upon the first signs of distress. If, however, the whole dose has been given by rapid intravenous injection with a syringe there is little that may be done. The patient should be laid flat and if pulseless or nearly so adrenalin should be injected *intravenously* in dose of 0.1 c.c. (1 to 2 minims) of 1:1000 solution diluted with water for the purpose of stimulating the heart and especially the right ventricle. For less severe reactions it may suffice to inject the adrenalin solution intramuscularly in dose of 0.5 to 1 c.c. (8 to 15 minims). In either case it may be necessary to prolong the stimulation by subsequent intramuscular injections. Subcutaneous injections are much less efficacious and oral administrations are useless.

Jackson and Smith [1a] have suggested intravenous injections of tyramin (parahydroxyphenylethylamin) in dose of approximately 0.001 gm. per kilogram of weight which, for an adult patient of average size, would be about 0.06 gm. or 1 grain. Tyramin stimulates the heart and produces a more prolonged and sustained use in systemic blood-pressure than adrenalin and may thereby prove useful for the treatment of collapse; I have had no personal experience with the drug, however, and under ordinary circumstances it is not as readily available as adrenalin.

At the same time atropin sulphate should be injected intramuscularly in dose of $\frac{1}{50}$th grain for the purpose of stimulating the circulation, relaxing the bronchi and possibly accelerating respiration by stimulation of the center and increased formation of carbon dioxid. If convulsions are present, atropin must of course be administered with great care in order not to overstimulate the motor areas and other higher divisions of the neural axis. Caffein and camphor are likewise efficacious by subcutaneous injection as heart stimulants and the primary object of treatment is to maintain cardiac and respiratory functions.

If the patent survives the acute shock, the purpose of treatment thereafter is to combat the effects of embolism and especially of the lungs. For this purpose he should be placed in bed, surrounded with hot water bottles if

the temperature is subnormal or a chill supervenes and sedatives administered especially if there is pain in the chest with coughing. For these purposes codein may be given, although small doses of morphin by subcutaneous injection are usually to be preferred. Counter irritation to the chest, front and back, is sometimes useful and especially dry cupping or hot turpentine stupes, the latter repeated at intervals.

Acute Vasoparetic Reaction or "Nitritoid Crisis."—One of the best known and most frequently mentioned of the toxic reactions sometimes following the intravenous injection of arsphenamin, neoarsphenamin and their substitutes, is the "nitritoid crisis," so designated by Milian[2] in 1912 because the lesions and symptoms resemble those produced by the inhalation of amyl nitrite. The phrase has since come into very general use and is frequently employed to cover any and all of the acute untoward reactions following the injection of the organic arsenical compounds. As a matter of fact, however, the reaction may be produced by the intravenous injection of various substances and as we will shortly discuss under etiology, may be caused by a variety of seemingly unrelated agents. The outstanding change is one of acute congestion apparently due to loss of vasomotor control, a condition of vasoparesis, and the term "vasoparetic reaction" would appear to be especially appropriate.

The *frequency* of these reactions is difficult to state and has varied greatly in the experience of different syphilologists. Undoubtedly they were more frequent prior to 1920 than at the present time and are apparently produced by injections of arsphenamin more frequently than by neoarsphenamin and sulpharsphenamin. Different lots or batches of arsphenamin and neoarsphenamin have been known to produce more of these reactions than other lots and the arsphenamins prepared by different laboratories vary in this regard. In 1912, Milian observed as high as 4.8 per cent. "nitritoid" reactions; in 1917 Jones and Gibson[3] found the incidence approximately 0.5 per cent. and I believe it may be stated at present that they occur in less than 1 per cent. of injections. Acute or immediate reactions of this kind are not ordinarily observed following intramuscular injections of arsphenamin or its substitutes and especially sulpharsphenamin, although such delayed reactions as nausea and vomiting and the acute central nervous system vasoparetic reaction developing a few days after injection have been produced by this route of administration. Dennie[1] states that he has never seen the reaction after ten thousand doses given to children over a period of four years, but it is not stated whether most of these injections were by the intravenous or intramuscular routes and, as just mentioned, the incidence is very much higher after intravenous than after intramuscular or subcutaneous injections.

Etiology.—The subject of the etiology of these reactions is still quite obscure; we know in fairly definite terms of several causes but little or nothing of the exact mechanism of their action. The outstanding and prominent lesion is one of acute vasodilatation with serous exudation and this change may be brought about by seemingly unrelated agents.

Milian has stated that the reaction was due to acute adrenalin insufficiency and Berward,[5] Hirano[6] and others have subscribed to this view. It is true that the injection of adrenalin may give prompt relief from the symptoms or prevent the reaction if administered prior to the injection of the arsphenamins by its well known vasoconstrictor effects, but this in itself is not proof that the reaction is caused by a sudden diminution of adrenalin in the blood presumably by an effect of the arsenical upon the suprarenal glands directly or through the sympathetic nervous system. Hirano studied the adrenalin store of rabbits' adrenals after intravenous injection of arsphenamin and neoarsphenamin employing the colorimetric method of Comessatti and also investigated a number of glands histologically. He concluded that large doses of these arsenicals produced a remarkable decrease of chromaffine substance, and of residual adrenalin and that in therapeutic doses arsphen-

amin caused partial exhaustion, while neoarsphenamin did not influence the adrenalin contents.

As stated in Chapter XLVI, Lucke and I observed histological changes in the adrenal glands of rabbits and rats injected with very large doses of arsphenamin and neoarsphenamin similar to those previously described by Pearce and Brown, but the changes produced by amounts corresponding to the doses ordinarily administered to human beings according to body weight, were almost without significance. Lucke, McCouch and I[7] then studied the subject along the lines of Hirano's investigations, but likewise with negative results. We injected rabbits intravenously with amounts of disodium arsphenamin ranging from 0.02 to 0.05 gm. and with neoarsphenamin in doses of 0.1 gm., per kilogram of weight which were therefore from two to five times the amounts ordinarily given human subjects at one time and at intervals of fifteen minutes to eighteen hours later extracted the right adrenal glands by the method of Folin, Dennis, and Cannon[8] and assayed them by the biological method of Elliott.[9] A considerable range of adrenalin values was obtained, but on the average, the amounts found were almost identical with the average of the adrenalin content of the glands of untreated control rabbits. In a second series of rabbits injected intravenously with two to twelve doses of arsphenamin and neoarsphenamin in amounts corresponding to the doses for human subjects according to body weight, the adrenalin content of the glands was practically unchanged and when examined histologically did not show any noticeable or constant alterations of the chromaffin reaction. The lipoids appeared to be very slightly increased after single large injections and slightly decreased after multiple injections.

These experiments, of course, do not exclude the possibility of arsphenamin and its substitutes producing acute temporary decrease of adrenalin in human subjects either by direct action upon the glands or through the sympathetic nervous system; they do indicate, however, that this action is improbable and at least show quite clearly that the glands and their adrenalin store are not constantly or perceptibly changed insofar as such may be studied experimentally. Recently Levy and Juster[10] have drawn attention to the frequency of "nitritoid" reactions among individuals with symptoms of adrenal insufficiency as apathy and asthenia; also among those with thyroid disturbances and they suggest that the "nitritoid crisis" may be due to disturbance of some of the endocrine glands. Juster[11] has especially emphasized the possibility of a simultaneous parasympathetic stimulation and sympathetic paralysis as a cause of these reactions and believes that injections of adrenalin afford relief by stimulating the sympathetic nervous system. He has observed the reaction more particularly among those in a vagotonic state and has re-named the symptom-complex the "vagotonic crisis." Flandin, Tzanck and Roberti[12] and other French syphilologists have likewise subscribed to the view that the "nitritoid crisis" is due to some disturbance of the sympathetic nervous system which in turn produces disturbances of certain of the endocrine glands including the adrenals. Rosen, Müller and Myers,[12a] observing that the intravenous injection of arsphenamin is followed by a decrease of leukocytes in the peripheral blood, believe that this effect and the influence of adrenalin upon the angioneurotic symptoms indicate that the drug influences the autonomic nervous system rendered hypersensitive by some constitutional factor or by syphilitic infection.

I think it is to be granted that the lesions and symptoms of the "nitritoid crisis" are due to a disturbance of the sympathetic nervous system insofar as the vasomotor nerves are concerned. This disturbance is characterized by immediate or almost immediate vasomotor paralysis which may be general or more or less localized. This effect upon the sympathetic nervous system is, however, a direct and primary one without involving in any essential manner the endocrine glands although it is to be granted that disturbances of these glands and more especially of the suprarenals, may render the sympathetic nervous system more susceptible to the toxic effects of the organic

arsenicals and other unrelated agents known to produce the vasoparetic reaction.

What produces this vasoparesis? Is it due to a toxic impurity in the drug? Is it due to a state of natural or acquired allergy to arsenic? Is it due to physicochemical factors involving the colloidal chemistry and interaction between solutions of the medicaments and the plasma of the patient? Before attempting to discuss these possibilities, it is clear that any explanation of the mechanism must satisfactorily meet the following two clinical facts in order to be acceptable: first, that some lots of arsphenamin and neoarsphenamin have produced the reactions when other lots prepared by the same laboratory did not and that chemical analyses and rat toxicity tests have generally failed to show any essential differences among them or to disclose the toxic agency in the former; secondly, that some individuals have developed the reaction when injected with the same compound in exactly the same manner as numerous others who escaped reactions. The question of etiology now resolves itself into what constitutes the toxic agency and why human beings vary in susceptibility to it.

In my opinion, the acute vasoparetic reaction or "nitritoid crisis" may be due either to toxicity of the medicament or to an abnormal change in the capillaries of the individual. In case of the former, reactions of this kind may be produced in human beings with a normal vasomotor system; in the case of the latter reactions may be produced in individuals with an abnormal vasomotor system by compounds perfectly well borne by the great majority of human subjects. In still a third group the reactions may be due to a combination of these two factors, namely, an abnormal vasomotor system and the injection of a compound containing arsenic in such a physical colloidal state as intensifies the physiological vasodilating effects of arsenic. My reasons for this opinion are as follows: The physiological action of arsenic is to produce paralysis of the capillaries with increased permeability and especially of the vessels of the splanchnic area. This has been known for many years, is a well-established fact in the pharmacology of arsenic and in 1912 Ricker and Knape[13] showed by direct microscopic observations of the capillary beds in living animals during the administration of arsphenamin and neoarsphenamin that both drugs caused a slowing of the blood stream, dilatation of the capillaries, stasis and hemorrhage. At the same time the heart is involved by a similar action of the arsenic upon the nerve ganglia and the pronounced and persistent fall in blood-pressure is due to cardiac failure and arterial vasomotor paralysis or depression, aided probably secondarily to some extent by diminution of blood volume by transudation of plasma due to increased capillary permeability.

Under normal or usual conditions this effect of arsenic following the intravenous injection of arsphenamin and its substitutes is not apparent or is so mild and fleeting as to produce but mild and temporary effects. But in some individuals with instability of the vasomotor system due to endocrine disturbances or factors of unknown nature, these physiological effects are greatly exaggerated resulting in the production of extreme vasoparesis or the extreme sensitiveness of the vasomotor nerves to the physiological effects of arsenic may be due in some cases to accumulation of arsenic in the tissues or to congenital or acquired hypersensitiveness to arsenic. As stated in Chapter XLVII, there can be little or no doubt that some individuals are naturally hypersensitive to arsenic just as others may be to quinin, cocain and other drugs; also that individuals receiving numerous injections of arsphenamin or one of its substitutes may develop an intolerance for the drug, either as a result of accumulative toxic effects or of the acquisition of

allergic hypersensitiveness. The results would be the same in either case, because cumulative toxic effects of arsenic would involve the nerves of the capillaries and allergy in man is characterized by vasomotor paralysis due either to a direct effect upon smooth muscle in general including that of the blood vessels or upon the vasomotor nervous system. In other words, the reasons why some individuals develop acute vasoparesis following injections of arsphenamin or one of its substitutes which produce no untoward effects in other individuals may be due to any one or a combination of these changes in the individuals themselves and not to the drug: (*a*) Because their sympathetic vasomotor nervous system is unstable by reason of endocrine or other disturbances resulting in increased susceptibility to the physiological vasoparetic effects of arsenic; (*b*) because arsenic has accumulated from previous administrations and produced a state of vasomotor instability or (*c*) because the individual has a natural congenital or acquired state of hypersensitiveness to arsenic which results in acute vasomotor paresis, either because of allergic sensitiveness of the smooth muscle of the capillaries or an effect upon the vasomotor nerves. Individual susceptibility may be due, therefore, to any one or several of three unrelated factors involving the capillaries direct or their nerves.

But why are some lots of arsphenamin or neoarsphenamin more likely to produce this reaction than others? As previously stated, some batches of arsphenamin have produced so many reactions of this kind that they could not be employed. What is even more mysterious is that other physicians have used the same lots with absolutely no untoward reactions. Chemical analysis and rigid animal tests of such lots have repeatedly shown in my experience no changes from the usual and average, although these do not exclude the possibility that impurities were present. In my opinion, the effects are due to arsenic either from the molecule of the drug or from an arsenical impurity. In other words, the mechanism of its toxic action would appear to be referable more to physical (colloidal?) changes affecting the vasomotor system than to chemical injury of the capillaries. But just what may be the exact nature of these physical changes I am unable to state. As reviewed in Chapters XLV and XLVIII, it is apparent that the concentration of the solution, its age before injection and rapidity of injection, the temperature of the water or saline solution employed for preparing solutions, the degree of shaking necessary to effect solution and, above all, the reaction of the solution, are factors of varying importance influencing and modifying the viscosity and probably other physical colloidal properties of the solutions and particularly solutions of arsphenamin. In my opinion, these factors influence primarily the physiological action of the arsenic. In some lots of arsphenamin the change may be due to manufacture and thereby explain vasoparetic reactions with a given lot in the hands of different physicians; in other and more numerous instances the changes may be brought about during the preparation of solutions and thereby explain why a given lot produces reactions in the hands of some physicians and not in the hands of others. I do not know the exact nature of these changes in the physical (colloidal?) chemistry of the arsenic of arsphenamin and its substitutes; neither do I know how it produces vasoparesis other than it appears to intensify the physiological vasoparetic effects of arsenic. I very much doubt if the reactions are due to intravascular agglutination, hemolysis or precipitation such as occurs when concentrated acid solutions of arsphenamin are injected intravenously, although, as previously described, the symptoms may be similar insofar as fall of blood pressure and pulmonary symptoms are concerned; the plasma is probably able to prevent the slight agglutinating

and hemolytic effects of dilute solutions of disodium arsphenamin slowly injected and there are no evidences at all of intravascular reactions of this kind from the injection of isotonic solutions of neoarsphenamin although this arsenical may produce the "nitritoid crisis."

In the final analysis, this acute toxic reaction may be due, therefore, primarily to an exaggeration of the physiological effects of arsenic of arsphenamin and its substitutes. In the majority of cases no ill effects are noted. In some, however, toxic reactions are produced either because the capillaries and the vasomotor nerves are unusually sensitive to the vasoparetic effects of arsenic or because the arsenical compounds undergo some change in the course of manufacture and in the preparation of the solutions as results in increasing the toxicity of the arsenic or in such physical (colloidal?) changes as greatly exaggerates its physiological effects upon capillaries.

Symptoms.—The symptoms are due directly or indirectly to the acute vasoparesis and may be of a most varied character according to the capillary beds involved and the degree of dilatation and exudation. As a general rule, the patient first complains of a peculiar metallic taste resembling ether, garlic, vinegar, etc. and of feeling queer with a sense of "fullness" of the head, pain in the gums and teeth, nausea and a burning sensation of the skin of the face and head and particularly of the lips and tongue; sometimes there is immediate vomiting. The face is flushed, particularly the cheeks and ears, and is accompanied by injection of the conjunctivae and eyelids with lachrymation and dilatation of the pupils, the eye symptoms being especially characteristic. Not infrequently the only symptoms are syncope followed by headache and nausea or immediate flushing and burning pain of the face, passing of the fingers through the hair, nausea and vomiting; in mild cases and especially if the injection has been slowly given and promptly interrupted, no other symptoms develop, leaving the patient badly frightened and a little weak but otherwise well.

In more severe cases, however, the tongue and lips become very much swollen and dusky red in color with husky voice and coughing due to swelling of the mucous membrane of the oral and respiratory tracts. The pulse at first rapid and bounding may become weak and rapid with marked pallor of the skin and profuse perspiration; retching and vomiting; loss of control of the sphincters, shallow respiration, coughing and backache may be present. The patient feels that he is going to die, certainly looks as if he may but rarely does. In some cases consciousness is lost for a brief time and convulsive twitchings may develop. Sometimes the skin and especially that of the chest and neck develops a "goose skin" appearance, the elevations gradually turning pink and developing into an urticarial rash which may be localized to the areas mentioned or involve other portions of the body.

As previously stated, these lesions and symptoms may be explained entirely by the sudden dilatation of the blood-vessels and especially of the capillaries; why the capillaries of the conjunctivae and skin of the face generally are primarily involved cannot be stated. Bargues[14] and others have described cases of localized "nitritoid crises" involving the arm and certain nerves following injections of neoarsphenamin. The capillary dilatation with serous exudation is likewise responsible for the swelling of the lips and tongue, the urticarial eruption and possibly of the dyspnea and cough by involvement of the bronchial mucosa. The succeeding pallor, rapid and weak pulse, perspiration and coma are probably due to splanchnic dilatation and cardiac depression and dilatation. Vomiting has been explained on the basis of congestive irritation of the vomiting centre or it may be due to the general meningeal and cerebral congestion evidently responsible for the feel-

ing of "fullness of the head" of which most patients complain. As reported by Keidel and Kemp[14a] cases of cardiac syphilis (aortic insufficiency and myocarditis) may especially develop alarming symptoms of sudden syncope with a greenish pallor, cold sweats, gasping respiration, bradycardia, reduction of blood pressure, etc., evidently associated with acute cardiac damage.

Hemorrhagic Encephalitis (Acute Cerebromeningeal Congestion and Edema). In rare instances, the cerebral and meningeal congestion produces more alarming and dangerous symptoms coming on two to four days later and constituting what Milian has designated as "*serous apoplexy;*" this condition is characterized by extreme congestion of the cerebral meninges, serous exudation with greatly increased cerebrospinal fluid pressure and in some instances, with minute hemorrhages in the meninges and substance of the brain. In German literature the syndrome is usually designated as "*hemorrhagic encephalitis.*"

In mild cases there may be only severe headache, fever and vomiting which pass off without special treatment. As a general rule the patient exhibits some signs of a "nitritoid crisis" at the time of injection, but recovers and all goes well until the third or fourth day when cerebral symptoms suddenly develop. As described by Sanphar,[15] Castello[16] Dennie,[17] Fraser and Duncan[18] and others, the patient becomes extremely restless and apprehensive followed by severe headache, edema of the face, vomiting and dyspnea; thereafter the patient becomes unconscious with signs of severe cortical irritation as clenched teeth, epileptiform convulsions or general twitchng, cyanosis, rapid and stertorous breathing followed later by shallow, irregular breathing as the respiratory center becomes exhausted. Coma, the Cheyne-Stokes syndrome, incontinence of urine and feces develop and death may follow in twenty-four to forty-eight hours.

In these cases, the spinal fluid shows the changes of "meningismus" or so-called "serous meningitis" being under increased pressure, normal in gross appearance but otherwise showing the pathological changes of syphilis.

Necropsy examination is likely to reveal an acute hyperemia of the meninges with disseminated punctate hemorrhages. Capillary hemorrhages may also be found in the liver and kidneys and the lungs may likewise show acute congestion with interstitial hemorrhages.

Ehrlich believed that these lesions and symptoms were produced by oxidation products and particularly by "arsenoxid" producing adrenal insufficiency. McDonagh believes that they may be due to toxins liberated from spirochetes and paralyzing the vaso-constrictor nerves. Dudley[19] believes that the most important cause is an insufficient supply of oxygen to the tissues—an anoxemia. Hitch[20] has also subscribed to this view believing that the widespread capillary hemorrhages afford a clear anatomical basis for the hypothesis and occurring in the lungs are responsible for the anoxemic state.

Treatment of the "Nitritoid Crisis."—The first step in treatment is, of course, to interrupt the injection if all of the solution has not been given. *The patient should then be laid flat* and the clothing loosened. A drahm or two of aromatic spirits of ammonia diluted with water should be given and in mild cases nothing more may be required. As a general rule, however, more treatment is indicated and since Milian first suggested *intramuscular or subcutaneous injections of adrenalin*, numerous reports have shown that this is the remedy of choice, as stated by Ravaut,[21] Darier[22] and other French syphilologists, as well as by Pollitzer,[23] Berman,[24] Meddis and Sterling[25] Beeson[26] and numerous other American syphilologists. Adrenalin in adequate dosage produces a constriction of the blood-vessels and especially of

the splanchnic area by stimulating the myoneural junctions of the postganglionic fibers of the sympathetic nerves and also stimulates the heart by action upon the terminations of the accelerator nerves in the muscle of this organ. It effects, however, are fleeting and several injections may be required but due care must be exercised against over dosage to avoid producing "delirium cordis."

Pituitrin may be also of some value and may be used along with adrenalin. It tends at first to produce a slight fall in blood-pressure by cardiac depression along with a slowing of the heart beats due to reflex vagus stimulation, but these effects are followed by a rise in pressure due to vasoconstriction through direct stimulation of the smooth muscle of the blood-vessels; Milian states that a combination of adrenalin and pituitrin (hypophysine) is good, since the effects of the latter are more prolonged. The dose is 1 c.c. (15 minims) of the liquor hypophysis (pituitary solution) by subcutaneous injection.

Atropin sulphate in dose of $\frac{1}{50}$th grain by subcutaneous injection has been especially advocated by Stokes[27] and Busman[28] and is particularly valuable for the prophylaxis of these reactions as has been already discussed in the preceding chapter. Atropin tends to relax the bronchi and thereby relieve the dyspnea and air hunger due to the acute congestion of the mucosa; in the dose advised it is also possible that the respiratory centre is stimulated with acceleration of the breathing rate and depth. Hanzlik and Karsner[29] state that atropin relieves the pulmonary symptoms by improvement in the circulation rather than by any effect upon the smooth muscle of the bronchioles.

Jackson and Smith[30] have found *tyramin* especially useful in the treatment of dogs severely poisoned by arsphenamin, observing that in dose of 0.001 gm. per kilo (corresponding to 0.06 gm. or 1 grain for an adult of average size) by subcutaneous or intramuscular injection, it stimulates the heart and produces a prolonged, sustained rise in the systemic blood-pressure.

My own practice has been to treat these cases as follows, in addition to laying the patient flat and giving aromatic spirits of ammonia diluted with water, as already mentioned: (*a*) The immediate intramuscular injection of 1 c.c. (15 minims) of adrenalin hydrochlorid (the usual 1:1000 solution) in the arm or gluteal muscles; (*b*) the immediate intramuscular injection of atropin sulphate in dose of $\frac{1}{50}$th grain. These are adult doses; children are given smaller amounts according to approximate weight. As a general rule, nothing more is required unless it is a second intramuscular injection of adrenalin in dose of 0.5 c.c. (8 minims) about ten minutes later. It is hardly worth while to give adrenalin by mouth. Whenever the physician has reason to expect the possible development of the acute vasoparetic reaction, adrenalin and atropin should be prepared beforehand ready for immediate injection and it is well for all physicians administering arsphenamin or its substitutes to have both drugs available and especially an *active* solution of adrenalin.

In severe cases accompanied by coma, it may be necessary to give adrenalin intravenously and for this purpose 0.1 c.c. (about 2 minims) well diluted with water or saline solution may be slowly injected; great care, however, is necessary when adrenalin is administered by this route.

In some cases persistent headache which may be accompanied by nausea, is very troublesome. These symptoms are probably due to increased intracranial pressure or "tension headache" for meningeal congestion and I have afforded prompt relief by the oral administration of sodium chlorid in dose of 1 gram (15½ grains) in salol coated pills or capsules every 5 or 10 minutes for 2 to 10 doses as suggested by Hughson[31] on the basis of the

investigations of Cushing and Foley.[32] Probably better results are to be obtained by the administration of magnesium sulphate as recently described by Fay[33] for the relief of intracranial pressure, in dose of 1½ ounces by mouth every fourth hour or 3 ounces in 6 ounces of water by rectal injection every fourth hour until the desired effect is obtained but with due care against producing excessive dehydration. In contrast with sodium chlorid, the magnesium salt is relatively non-diffusible through the intestinal wall, and, not being absorbed into the blood stream it exerts its entire effect on the vascular bed about the intestinal wall; hence, the direct extraction of fluid from the circulation and the secondary withdrawal of ventricular or tissue bound fluids bring about dehydration, for the circulation calls on all the available body fluids to compensate for the depletion in blood volume by way of the intestinal tract.

Treatment of Hemorrhagic Encephalitis.—These have been successfully treated by repeated spinal punctures (at least every twelve to eighteen hours) to reduce the pressure along with the intravenous and intramuscular injection of adrenalin. As soon as symptoms develop, spinal fluid should be drawn and 0.1 c.c. of adrenalin well diluted injected intravenously. It is well to follow this within ten to fifteen minutes by intramuscular injections of 0.5 to 1 c.c. of adrenalin and 1 c.c. of pituitrin. Urotropin in dose of 1 gram and caffein in dose of 0.2 gram in 15 c.c. of sterile water may be injected intravenously for dieuretic effects. Subsequent doses of these drugs must be given according to circumstances keeping in mind the physiological and toxic effects especially of adrenalin, and carefully avoiding over stimulation of the heart. It may be worth while to inject intravenously 1 gram of sodium thiosulphate or 3 grains of thiosinamin dissolved in 10 c.c. of sterile distilled water. I will shortly discuss the toxicity and action of these drugs with more detail in connection with arsenical dermatitis and jaundice. It would also appear that the intravenous injection of hypertonic solutions of sodium chlorid intravenously may reduce intracranial pressure, as suggested by the investigations of Weed and McKibben[34] and of Weed and Hughson;[35] the effect may be then prolonged by the oral administration of sodium chlorid or better still, by the oral or rectal administration of magnesium sulphate.

On the basis of the anoxemia hypothesis, it may be worth while to administer oxygen by continuous inhalation and the stomach may be washed out and sodium carbonate left in it on the assumption that acidosis may be partly responsible.

Gastro-intestinal Reaction. *Etiology and Symptoms.*—As previously stated, immediate nausea and vomiting sometimes follow the intravenous injection of arsphenamin, neoarsphenamin or sulpharsphenamin and especially if the injections are given soon after a meal; vomiting alone without nausea is not uncommon. Doubtless these effects are at times due to excitement and the ether-like taste and subside in a few minutes.

In a larger group of individuals, however, there are practically no immediate symptoms, but within twenty-four hours of injection and usually within one to four hours, gastro-intestinal symptoms develop among which nausea, vertigo, headache, thirst, vomiting and diarrhea are to be mentioned. Sometimes the temperature is elevated one or two degrees with pain in the extremities or "stab" pains in the back. These symptoms may be so mild as to merely make the patient feel "queer" or there may be repeated chills, numerous attacks of vomiting and profuse and protracted diarrhea.

I believe that reactions of this kind developing immediately or within a few hours of the time of injection are due to the vasoparetic effects of the

arsenic of the compound or of an impurity and that the symptom-complex is essentially a gastro-intestinal type of the acute vasoparetic reaction or "nitritoid crisis" in which the capillaries of the meninges and brain and of the intestinal mucosa are primarily involved. It is possible that a temporary acute cerebro-meningeal congestion is responsible for the headache, "queer" feeling in the head, vertigo, nausea and vomiting, the latter being due to a disturbance of the vomiting center; acute congestion of the gastro-intestinal tract with increased capillary permeability and serous exudation may be responsible for the "looseness of the bowels" or a well marked diarrhea, vomiting and thirst. There are no evidences of corrosive effects in the mucosa of the intestine and the symptoms are quite similar to those of acute poisoning from any arsenical compound.

Mild reactions of this kind are probably the commonest of all the toxic manifestations following the intravenous injection of arsphenamin and its substitutes. Women are especially likely to show symptoms of this kind and doubtless constipation and endocrine disturbances are important contributory causes. The incidence of reactions appear to be as high with neoarsphenamin as with arsphenamin but different lots of these compounds have varied greatly in the production of nausea, vomiting and diarrhea; that is, some lots of either produce more of these reactions than others, although no difference in toxicity for the rat could be determined. Not infrequently this gastro-intestinal reaction does not develop until six or more injections have been given suggesting either an accumulative toxic action of arsenic or the acquisition of hypersensitiveness to the drug. Sometimes the first course of twelve to fifteen injections of neoarsphenamin produce absolutely no ill effects whereas after the first injection of the second course following a "rest" of four to six weeks, nausea and vomiting may occur.

In addition to this type of diarrhea developing within a day or two of injection, there is another form which sometimes develops at a later time and in connection with dermatitis and jaundice. This type of diarrhea may be due to the effects of arsenic upon the intestinal mucosa, or as suggested by Stokes and Cathcart[36] to infection of the tract and especially of the colon with streptococci derived from areas of focal infection whose activities are stimulated by the surgical removal of these foci or by the administration of arsphenamin and its substitutes. I shall later refer again to this type of diarrhea in a discussion of arsenical dermatitis, as likewise to *stomatitis* which sometimes is present in association with the cutaneous lesions.

Treatment.—As previously stated in Chapter L, the gastro-intestinal reaction may be frequently rendered so mild as to prove free of annoyance if proper attention is given to the state of the bowels and particularly relief from constipation, proper hygiene of the mouth, and if the injections are given two hours or more after meals. When there is a tendency for the development of colic and diarrhea under these conditions I have found it advantageous to give 10 grains of sodium bicarbonate and 10 grains of bismuth subnitrate about an hour before injection repeating the bismuth if necessary upon the first signs of diarrhea. In severe headache, diarrhea and vomiting, it is sometimes necessary to administer adrenalin and I have observed prompt relief afforded by the intramuscular injection of 0.5 c.c. (8 minims) of the usual 1:1000 solution. In mild reactions of nausea, one or two vomitings and colic, relief is sometimes afforded by drinking an ounce or two of cold ginger ale or by sipping hot, well-seasoned broth.

In some cases it is necessary to give the patient a "rest" from arsenical treatment for several weeks or to reduce the dosage. Treatment can usually be continued with bismuth or mercury without ill effects and sometimes if

the reactions are being produced by arsphenamin, treatment can be continued with neoarsphenamin or sulpharsphenamin or the reverse.

Protein and Colloidal Shock Reaction. *Etiology and Symptoms.*—Frequently occurring with this gastro-intestinal reaction but sometimes developing alone from one to four hours after injection are a group of symptoms consisting of moderate fever (usually 100° to 102°F.), sometimes accompanied by perspiration, chilliness or a distinct rigor, headache and nausea which I believe may be due to a type of protein or colloidal shock reaction produced by the effects of intravascular hemolysis or the use of sterilized stale water or saline solution containing dead bacteria or molds and the products of their disintegration. During the early part of the reaction the leukocytes are frequently increased in number and since the reaction resembles that usually observed after the intravenous injection of typhoid vaccine, peptone and other protein substances in the non specific treatment of arthritis, etc., I have applied the term "protein shock reaction" to the syndrome since it appears to be a reaction apart from the effects of the arsenic of the compound.

This type of reaction is especially likely to follow the intravenous injection of solutions of disodium arsphenamin in water. While the plasma affords a considerable degree of protection against intravascular hemolysis, yet at the site of injection and particularly rapid injection with a large needle, it is likely that some hemolysis occurs as the solution comes in contact with the blood and sufficient for producing a mild reaction of this type. The reaction may occur likewise after the intravenous injection of neoarsphenamin and sularsphenamin and especially the rapid injection of the usual doses dissolved in 20 c.c. or more of water.

Hemolysis, however, is probably not solely responsible for these reactions. I am convinced, as stated in Chapter XLV, that reactions of this type may be caused by the use of stale distilled water or saline solution prepared with such water, sterilized before use of course, but containing dead bacteria or molds, the ill effects being due to the proteins of these organisms as stated by McIntosh and Fildes rather than to their toxins, which Wechselmann and other early writers on salvarsan reactions thought may be responsible ("Wasser-fehler"). Heating water and saline solution to 100°C. or higher is sure to destroy bacterial toxins, but is not sufficient for the removal of the proteins of the bacteria and molds themselves. The use of sterilized stale water (distilled or otherwise) is particularly important in this connection as such water may be contaminated with bacteria or molds and experience teaches that it requires but infinitely small amounts of these products injected intravenously to elicit shock reactions of this type. For this reason sterilized *fresh* water (preferably distilled) should be employed for the preparation of solutions for intravenous injection. Water freshly distilled sealed in ampules and sterilized cannot of course become contaminated as long as the ampules remain intact, but it is possible for stale water to produce reactions of this kind when the ampules are several months or years old and especially if chemical substances are dissolved out of the glass.

As previously stated, a colloidoclastic reaction of this kind is likely to occur along with reactions due to the arsenic and particularly the gastro-intestinal reaction; it is not always possible, therefore, to separate and recognize the protein or colloidal reaction as a distinct entity, but I believe that it is well to keep in mind the possibility of its occurrence alone or associated with reactions of other origin.

Treatment.—Mild reactions of this kind do not ordinarily require any special treatment and usually subside in an hour or two. Chilliness or a distinct rigor may require the patient to go to bed with the application of hot water bottles and to take hot drinks; a few drams of aromatic spirits of

ammonia in an ounce or two of hot water is sometimes helpful. In other words, the treatment is purely symptomatic and offers no difficulties.

Dermatitis and Allied Reactions.—Probably the most annoying of all the toxic manifestations following the administration of arsphenamin and its substitutes are the various rashes of the skin and mucous membranes with accompanying symptoms. The severe types of these reactions and especially exfoliating dermatitis, are likewise the most dangerous, as death not infrequently follows the development of these lesions. A very large literature has accumulated upon the subject since 1912 composed mostly of case reports and numerous classifications of the rashes, as well as theories of their etiology, have been proposed within recent years.

Classification of the Skin and Mucous Membrane Lesions.—As is now generally well known, quite a variety of rashes with subjective symptoms may follow the administration of arsphenamin, neoarsphenamin, silver arsphenamin, sulpharsphenamin and other organic and inorganic compounds of arsenic. Since the widespread use of arsphenamin and its substitutes in the treatment of syphilis the incidence of these reactions has naturally increased, but to the best of my knowledge none of the various skin rashes are peculiar to arsphenamin, neoarsphenamin or sulpharsphenamin alone and all have been described following the administration of various organic and inorganic compounds of arsenic before the discovery of arsphenamin and its substitutes.

The rashes that may follow the intravenous injection of arsphenamin and its substitutes are extremely varied and so many types may be encountered that it would appear almost useless to list them all on a morphological basis. As stated by Morrow[37] in discussing drug eruptions in general "a classification based upon the anatomical form of the lesions produced by drugs is impracticable. The very multiformity of the lesions forbids any such attempt, for while the irritant action of a particular drug may, in one individual be manifested by a single elementary lesion, the same drug may produce, in another individual, eruptive elements of dissimilar forms." The same is true of the skin lesions produced by the organic arsenicals now in common use for the treatment of syphilis. However, these reactions may be classified as follows:

- **Mild and early skin lesions**
  - Simple erythematomacular rash
  - Urticaria
  - Herpes
    - Simplex and especially of the lips
    - Zoster
  - Exacerbation of syphilitic rashes (Jarisch-Herxheimer reactions)
  - Pruritus
- **Sever and late skin lesions**
  - Dermatitis
    - Scarlatiniform erythema with desquamation
    - Erythema multiforme
      - Papular
      - Vesicular
    - Lichen planoid
    - Acute exfoliative
  - Purpura
    - Simplex
    - Rheumatica
    - Hemorrhagica
- **Mucous membrane lesions sometimes accompanying severe skin rashes**
  - Stomatitis and aplastic anemia
  - Exfoliative ileo-colitis
  - Bronchitis and broncho-pneumonia
  - Exfoliative conjunctivitis
  - Vaginitis
- **Chronic and recurrent skin lesions**
  - "Fixed" arsenical rashes
  - Pigmentation
    - Arsenical melanosis
    - Argyria
  - Arsenical hyperkeratoses
    - Palmar
    - Plantar

Stuhmer[38] has classified arsphenamin dermatitis under three headings: (1) Acute vasotoxic reactions, embracing those developing within a few hours to one or two days after injection as the acute, urticarial and erythematous rashes as well as the "fixed" arsphenamin eruptions; (2) subacute, anaphylactoid eruptions appearing from six to twelve days after the first injection and resembling serum sickness and also including the recurrent exanthems described by Nathan, in which the rash appears from ten to fourteen days after the first injection, fades within a few days and then partially recur; and (3) chronic dermatitis divided into early and late forms. The early form manifests itself after the fifth or sixth treatment; the late form, from several weeks to two or three months after the completion of a course of injections. These eruptions represent the severest types of dermatitis.

Incidence and Mortality of Dermatitis and Allied Reactions.—With so formidable an array of the skin and mucous membrane lesions known to follow the administration of the organic arsenical compounds one may readily enough acquire the impression that they must be of very frequent occurrence. But such is not the case insofar at least as arsphenamin and neoarsphenamin are concerned. As a matter of fact, however, the exact incidence of these toxic reactions cannot be expressed because the milder lesions do not ordinarily attract more than passing notice and with a few exceptions have not been reported. With the severer rashes, however, the incidence would appear to be not greater than one reaction to every 500 to 1000 injections of arsphenamin and neoarsphenamin as shown by the following reports; sulpharsphenamin however, has produced a higher incidence:

In 1917 Harrison[39] reported the occurrence of 124 cases of dermatitis in the course of 80,000 injections of arsphenamin to 10,000 patients. Of these twenty-six were severe, twenty four moderately severe, and seventy-four mild or fleeting. There were eight deaths or a mortality of 30 per cent. among the severe cases.

Parnell and Fildes[40] observed 38 rashes among 1250 men receiving 6588 injections of neoarsphenamin. Of these 12 were erythematous, 14 macular, 4 papular, 2 follicular, 1 polymorphic and 9 unclassified. In 2 cases, jaundice co-existed, but the rashes were mild in all but 1 case.

Moore and Keidel[41] have reported 23 reactions developing from 1914 to 1920 among approximately 9000 cases receiving about 47,000 injections of two different brands of arsphenamin, two brands of neoarsphenamin and one of sodium cacodylate. Of these 23 cases the rashes were mild in 5 and severe in 18, with 5 deaths or a mortality of 27.7 per cent. among the latter group. Moore in a personal experience covering 8000 injections of neoarsphenamin observed only nine cases of dermatitis, none being severe and with no deaths.

Stokes and Cathcart[42] have reported 38 cutaneous reactions of various types in the course of approximately 44,000 injections of arsphenamin in the Mayo Clinic. Of these 33 were studied in detail and 9 classified as severe dermatitis, 12 as moderate dermatitis and 12 as mild dermatitis. There were 2 deaths in the group of 9 severe cases or a mortality of approximately 22 per cent.

Sulpharsphenamin, however, may produce a higher incidence of dermatitis. Belding,[43] for example has recently reported an incidence as high as 16 per cent. in a group of adults and children treated with intravenous and intramuscular injections. My own experience with this compound has been similar, although the rashes have been mild with no cases of severe exfoliative dermatitis; the tendency of sulpharsphenamin to produce rashes is similar to that of arsenophenylglycin and for this reason I have learned to reserve the drug for the treatment of only those cases of syphilis to whom intravenous injections of arsphenamin and neoarsphenamin cannot be given. Of interest in this connection are the observations of Klauder[44] who noted a particular tendency for the development of dermatitis among patients in whom, through faulty venipuncture, some neoarsphenamin or arsphenamin was injected outside of the vein with resulting local reactions and suggesting that subcutaneous injections may be in some unaccountable manner particularly predispose to dermatitis. In my experience with sulpharsphenamin, however, the incidence has been as high after intravenous as after intramuscular injections and it can be stated that insofar as arsphenamin and neoarsphenamin are concerned the technic of administration bears no relation to the incidence of these reactions.

It would appear, therefore, that the general incidence of toxic skin and mucous membrane reactions after injections of arsphenamin, silver arsphenamin and neoarsphenamin is from 0.1 to 0.2 per cent. or one reaction to every 500 to 1000 injections. The mortality among the severe cases of the exfoliative dermatitis type has varied from 20 to 30 per cent. and for this reason exfoliative dermatitis is to be regarded as one of the most dangerous of the toxic reactions caused directly or indirectly by injections of the arsenical compounds.

Clinical Considerations of the Lesions and Symptoms.—Before entering upon a discussion of the etiology of these toxic reactions, it may be well to reverse the usual order of presenting the subject and first consider them briefly from the clinical standpoint which aids materially in an understanding of the causes.

As already mentioned in connection with the acute vasoparetic reaction or "nitritoid crisis" an *erythematous rash* is sometimes observed during or immediately after the injection over the chest and spreading to the neck and face. Sometimes this rash results in an urticaria but it usually disappears along with the other symptoms. More commonly a dusky red *erythematomacular rash*, blanching upon pressure, appears during the first week or two of treatment on the arms and legs and then extending over the body and sometimes involving the buccal mucosa. Slight transitory edema of the feet may accompany the rash as well as slight fever, malaise and nausea. As a general rule, the rash and symptoms disappear within two or three days with or without desquamation. It is stated by Moore and Keidel and others that further injections of the same or different drugs may be safely given, but I am personally always apprehensive of the development of one of the severer forms of dermatitis and never continue with the administration of the same drug but employ bismuth, mercury or another arsenical compound.

Urticaria may develop during the acute vasoparetic reaction or "nitritoid crisis" or within two or three hours after injection. In my experience it has usually developed after prolonged treatment with arsphenamin or neoarsphenamin, but may be seen after the first dose or two of these drugs and especially of sulpharsphenamin. The wheals last only a few days, but in exceptional cases may persist for a week. Aside from the itching, constitutional symptoms are not present. Having once occurred, urticaria is likely to occur again after repeated injections of the same drug, but in some cases it does not reappear; it is my practice, however, always to discontinue treatment with the drug responsible for the rash and employ another kind of arsenical compound which curiously enough may not produce the rash, or continue treatment for a while with bismuth or mercury before returning to the arsenicals.

Emery and Morin[45] and Saphier[46] have described cases of extensive urticaria accompanied by fever, adenitis and joint pains developing several days after injection and regarded as anaphylactic reactions because of the resemblance of these lesions to "serum sickness;" Moore and Keidel state that they have not observed reactions of this kind and neither have I up to the present time.

Herpes simplex and *herpes zoster* are rare types of rashes following the injection of arsphenamin and its substitutes. Herpes simplex may be severe, as in one case cited by Moore and Keidel in whom the chin, lips, tongue and buccal surfaces were literally covered with large herpetic lesions. Severe herpes, however, is rare although mild herpes is common but seldom noted since it causes little annoyance and the patient may not complain. Labial herpes is particularly likely to occur after the first dose, following which it

seldom reappears. Herpes zoster is rarer than herpes simplex and in some cases, at least, may be a coincident and accidental condition rather than a toxic arsenical reaction.

Herxheimer skin reactions in this connection refer to the accentuation of the rashes of acute early syphilis during the twenty-four hours following the administration of full doses of arsphenamin or one of its substitutes; with small doses the reaction may be avoided. The macular and papular syphilitic rashes become accentuated with increased reddening and swelling and occurring so soon after an injection may be mistaken for a toxic arsphenamin rash. As is well known, the same effects may be produced by mercury as originally described by Jarisch, Jadassohn, Herxheimer, Kraus and others.

Pruritus, or itching, is of particular importance as a prodromal symptom or danger sign of severe dermatitis if treatment with the arsenicals is continued. It is usually generalized and appears within twenty-four hours after injection, disappearing in a few days if treatment is stopped. Sometimes the itching is especially marked in the palms of the hands and may be accompanied by slight erythema. *Paresthesia* frequently accompanies pruritus and especially of the feet the patients stating that their feet feel "asleep;" the finger tips may be also involved and especially when the arms are stretched, but I will refer later to these symptoms in a fuller discussion of arsenical polyneuritis.

The essential lesion of the late and severe rashes is an inflammation of the skin—a dermatitis—developing one to fourteen days after injection with an average of 4.6 days as stated by Moore and Keidel in thirteen cases in which the time of appearance of the rash could be determined with certainty. As a general rule, the dermatitis develops during a course of treatment after six or more injections have been given; severe dermatitis has developed, however, after the first injection.

The rash may assume a wide variety of appearances responsible for the use of many different names for designating different lesions of essentially the same process. For example, the rash may appear suddenly as a *scarlatiniform erythema* of the extremities, gradually involving the trunk and disappearing in a few days, leaving a fine branny desquamation with entire exfoliation of the skin of the palms and soles of the feet; or the rash may be *morbilliform*, expecially in the trunk, or resemble the papular and vesicular varieties of *erythema multiforme*.

Sometimes the papules are entirely follicular, resembling *lichen ruber pilaris* and several writers, as McCaffery,[47] Frei and Tachan,[48] Buschke and Sklarz,[49] Smith[49a] and others have described cases in which the eruption closely resembled *lichen planus*. Sometimes the papular eruption is accompanied by a *pemphigoid eruption* of large vesicles and blebs which particularly involve the hands and feet.

These maculopapular and especially the vesicular eruptions, sometimes limited to the extensor surfaces of the arms and legs but more usually rapidly spreading until the whole body is involved, are followed by marked scaling and exfoliation—the condition well known as *dermatitis exfoliativa*. The skin of the entire body may be desquamated in large flakes and sometimes an entire palmar or plantar surface comes away intact. The rash is always accompanied by itching which may be intense and very distressing. Usually the exfoliation is complete in three or four weeks, but in some cases healing may take much longer and in occasional cases several exacerbations may occur in the same patient with exfoliation at intervals over several months. Fraser and Duncan have given the following excellent description of this severe dermatitis:

"The eruption usually starts on the flexor aspect of the forearms, next appearing on the face. In a very short time it spreads all over the body. At first it appears as a dark-colored scarlatiniform rash which rapidly becomes confluent. Small vesicles appear in the folds behind the ears, at the sides of the nose and on the neck. Blebs and pustules form all over the body, and their rupture causes crusting and scaling. Itching is very troublesome and is a source of infinite annoyance to the patient. There may be complete loss of hair on the scalp and shedding of the eyelashes and eyebrows.

"There is very extensive exudation into the skin and a characteristic puffiness and swelling of the face and head. The eyelids become so swollen and the face so puffy that the malar eminences practically meet the eyebrows, the eyes have disappeared from sight and the patient is unable to see. The conjunctivae are very infected and inflamed, the eyes feel sandy and lacrymation and photophobia are exceedingly troublesome. Transient blindness with edema of the optic discs may occur.

"A weeping eczema is usually present behind the ears, at the nasal folds and folds of the eyelids, and involving the lips, axillae, pubis, scrotum and perineum. Pyemic abscesses are common in severe cases and appear with alarming rapidity and persistence. Adenopathy is general and well-marked and occasionally the glands in the axillae break down.

"The skin at first becomes lobster-red and later reddish-brown. As exfoliation starts the skin settles down to a deep brown pigmentation and becomes thin and atrophic. The puffiness and general oozing and pain in the half-closed eyes and the very severe itching of the skin causes loss of sleep and the patient's health is soon seriously affected.

"In some cases constitutional symptoms may be slight but as a rule they are exceedingly severe. There is a high pyrexia accompanied by persistent headache, diarrhea, retching of the most trying severity and vomiting of bile-stained material. The tongue is dry, brown and heavily coated and the patient passes into the typhoid state. He is delirious and restless and often, if not closely watched, will get up and stagger about the room.

"In severe cases it is not unusual for the eruption to become hemorrhagic in places after the dermatitis has progressed for some time. When this happens the adenopathy is well marked and the glands particularly liable to break down.

"Lung complications are particularly fatal; pulmonary edema and bronchopneumonia are frequent complications in fatal cases.

"The patient becomes very emaciated and bed-sores are often trying and difficult to avoid or keep clean. Recovery is slow and convalescence protracted. When exfoliation is progressing the bed clothes are one mass of dry flakes and scales of considerable size. The skin thereafter is glazed, bronzed, thin and atrophic. Later it assumes a beautiful pinkish hue. The patient's appearance is so changed that his own friends may fail to recognize him. His features seem to have lost their proportion and he looks like an entirely different person. He returns to normal, however, in a month or two. The appetite returns sooner than one might expect and very often the patient will eat voraciously. Depression is a characteristic feature and often persists after the patient is eating well. Hyperkeratosis of the palms and soles frequently develops and these are the last to desquamate. Thick epidermal plates come away late during convalescence."

Polyneuritis and *jaundice* are sometimes present and *skin infection* with secondary rises of temperature are always likely to occur, especially in the weeping eczematous cases with cracks and fissures of the skin. It is sometimes impossible to prevent scratching and the introduction of staphylococci and streptococci which sometimes produce furuncles and carbuncles of serious import. Moore and Keidel, Stokes, and Cathcart and others have recorded several deaths from these secondary infections giving the severe types of this dermatitis a mortality of 20 to 30 per cent.

Of even more serious character is the development of *purpura;* two of four such cases recorded by Moore and Keidel succumbed. Jarecki[50] has classified these cases as those (*a*) showing small isolated hemorrhages from the gums, epistaxis and hemoptysis; (*b*) simple purpura; (*c*) purpura rheumatica and (*d*) acute purpura hemorrhagica which is very dangerous. Fortunately purpura is a rare reaction, but additional cases have been reported by Labbé and Langlois[51] Rabut and Owry[52] Florand,[53] Feit,[54] Calloman,[55] Weil and Wall,[56] Smith[56a] and others. More cases have occurred abroad than in America and neoarsphenamin has been apparently the most frequent cause; the one fatal case in my own practice occurred after eight injections of this compound. O'Leary and Conner[56b] however, have recently recorded two cases due to sulpharsphenamin.

In addition to these rashes, the majority of patients have an irregular and intermittent *fever* of 100° to 105°F. lasting for several weeks due to the secondary skin infections, focal infection, bronchopneumonia, etc.; also the accompanying increased pulse rate, respiratory changes, loss of appetite, etc. In relatively mild cases without focal or secondary infections the entire course of the dermatitis may be afebrile. Stokes and Cathcart have observed fever in a number of cases preceding the cutaneous eruptions and are of the opinion that this symptom is due in some cases to focal infection (apical abscesses, diseased tonsils, etc.) rather than to the cutaneous eruptions.

During the height of severe exfoliating dermatitis neighboring mucous membranes may share in the process as *exfoliating acute conjunctivitis, exfoliating vaginitis* and temporary *deafness* from exfoliation of the skin of the external auditory canal. *Diarrhea* due to acute ileocolitis occasionally develops during the course of the cutaneous reaction which may be due to arsenic or to secondary streptococcus infection as described by Stokes and Cathcart.

The exfoliating process may also involve the mucosa of the tongue and cheeks and severe *stomatitis* may complicate the cutaneous lesions. Stokes and Cathcart have reported 6 cases in their series; in 3 the stomatitis was mild and in 3 severe. One of their severest cases was accompanied by a relatively mild cutaneous reaction and in both cases reported by Moore and Keidel,[57] due to neoarsphenamin and associated with aplastic anemia, there was no dermatitis at all. In the mild cases there is little more than redness and dryness of the mucosa, but in the severe cases the gums, lips, cheeks and posterior wall of the pharynx may be involved with exudates, ulcers and hemorrhages due to secondary infection with the fusiform bacillis and spirochete of Vincent's angina.

Cases of stomatitis have also been reported by Görke[58] and Laurentier,[59] the latter drawing attention to the tendency for arsenical stomatitis to involve the fauces and pharynx with conjunctivitis and otitis while in mercurial stomatitis the front of the mouth and gums are especially involved. In dermatitis exfoliativa the *kidneys* are involved in about 80 per cent. of cases. Albumin and casts may be present in the urine and likewise blood in cases of purpura. Moore and Foley[60] have described four cases of severe reactions following the administration of arsphenamin with unusual blood pictures characterized by leukopenia, eosinophilia and an increase in the large lymphocyte and transitional groups, together with evidence of destruction of bone marrow. According to these investigators arsphenamin has a selective toxic and stimulating action on bone marrow and in one fatal case there was found at necropsy a markedly aplastic bone marrow showing degenerated cells and absence of the more mature forms of the myelocytic series. In the fatal cases studied by Moore and Keidel, necropsies showed markedly aplastic bone-marrow, with, as the outstanding feature, an almost complete absence of orderly leukopoietic centers. Nathan[61] has described leukopenia and a decrease of the polymorphononuclear neutrophilic leukocytes in cases of simple erythema and in severe dermatitis, leukocytosis due to increase of eosinophils and polymorphonuclears. Eosinophilia has also been observed by Hofmann,[62] Lathan[63] and by Stuart and Maynard[64] in cases of this kind and Feinberg[65] has reported an additional case of aplastic anemia following the administration of neoarsphenamin. Rosenbloom[66] has recently sounded a warning against the administration of arsphenamin in cases of hemophilia owing to the influence of this drug upon reducing the coagulation time of the blood. Desaux and his associates[67] state that a slight degree of acidosis may be present in severe cases of the arsenical erythrodermias.

I have reviewed these blood changes with considerable detail because I believe that they have an important bearing upon the etiology of arsenical dermatitis and the prognosis of individual cases since profound changes of these kinds in the bone-marrow may evidently reduce resistance to bacterial infection and readily enough introduce the factor of infection focal or otherwise, as one of considerable importance, as so well described by Stokes and Cathcart, to which reference will be later made in a discussion of the etiology of these reactions.

And now brief mention may be made of the more chronic and recurring lesions of the skin produced by the administration of arsphenamin and its substitutes. All of them have been known for many years before the discovery and use of arsphenamin in the treatment of syphilis following the administration of various organic and inorganic compounds of arsenic. Fortunately they are of rare occurrence and in view of the very large amounts of arsphenamin, neoarsphenamin and their substitutes administered to individual patients at the present time over comparatively brief periods it is a wonder that they are not more frequent.

Probably the most interesting of these are the so-called "*fixed arsenical exanthems*" described by Fuchs,[68] Schönfeld,[69] Leibkind,[70] Thibierge and Mercier,[71] Nagëli,[72] Kraus,[73] Guttmann,[74] Stokes and Cathcart,[75] Cabassi,[76] Klauder[77] and others. In some of these cases an urticarial patch on the arm, in the axilla, inguinal or popliteal spaces, on the chest or some other part of the body may develop after each injection followed by disappearance and the gradual production of a pigmented spot. As stated by Wise and Parkhurst,[78] these eruptions are very much like those seen in persons susceptible to antipyrin and phenolphthalein. They "consist of from one or more to several dozen sharply circumscribed, slightly elevated, smooth plaques, which may be pink, red, yellowish or brown; sometimes they leave no trace, at other times a moderate grade of pigmentation." The point of special interest in these "fixed" arsphenamin rashes lies in the fact that they tend to relapse and recur *in situ* after each injection. According to Stühmer they are caused by a combination of the "oxids" produced from arsphenamin in union with serum proteins which he calls "oxid-toxin."

In some cases the area becomes chronically inflammed with the production of a scaly, eczematous, lichenified patch. Eruptions resembling lichen planus following the injection of arsphenamin have been described by Kleeberg,[79] Buschke and Freymann,[80] Keller[81] and others.

Arsenical melanosis, or pigmentation, as well as palmar and plantar *hyperkeratoses* have been observed by Philip,[82] Hofmann,[83] Heller,[84] Klauder and others following the prolonged administration of arsphenamin and neoarsphenamin; in Klauder's case the pigmentation occured in the skin of the trunk of a man receiving a total of 100 injections of arsphenamin and neoarsphenamin before the discoloration became apparent. These lesions differ in no way from the lesions produced by other forms of arsenic which are of uncommon occurrence but well known and described.

Of special interest in this connection is the subject of *argyria* following the prolonged intravenous injection of silver arsphenamin and silver neoarsphenamin. As is well known the prolonged internal administration of silver nitrate and other inorganic salts of silver may result in local or generalized pigmentation or argyria; the organic silver compounds, however, are much less likely to produce this accident. Apparently when the silver exists in a compound in a non-ionizable form there is much less danger of the production of argyria and such is true in the case of silver arsphenamin and silver neoarsphenamin. Lochte[85] reported a supposed case of argyria following intravenous injections

of silver arsphenamin but apparently he did not see the case himself and it may have been one of arsenical pigmentation; Kogoj[86] more recently, however, appears to have observed a true case of argyria along with arsenical pigmentation in the case of a girl, age 23, receiving three courses of treatment of which the first consisted of 12 injections of silver salvarsan and the second of 11 injections of neosalvarsan and mercury. The same number of injections of neosalvarsan and mercury was given during the third course. This information was given by the patient herself and the exact quantities of the drugs injected were not ascertained. During the third course of treatment she noticed a gray discoloration of the whole body excepting the palms and soles, unassociated with any discomfort. When examined by Kogoj the mucous membranes of the mouth, lips, tongue and conjunctivae were of a diffuse, dark gray color; the genitals were of a dark brown color. Examination of sections of skin showed a marked increase of the melanotic pigment and the formation of dark brown granules; tests for arsenic proved negative. Kogoj thoroughly reviews the literature upon arsenical pigmentation and concluded that in this case the discoloration was due to arsenic as well as to silver.

Myers[87] has failed to produce argyria experimentally in rabbits and rats by a large number of injections of silver arsphenamin; in experiments conducted for me by Dr. Harkins consisting in the injection of rats with twelve or more doses of silver arsphenamin and keeping the animals exposed to sunlight, no discoloration of the skin or mucous membranes was apparent, although rats injected intraperitoneally regularly showed pigmentation of the parietal and visceral peritoneum.

In view of the fact that large amounts of silver arsphenamin have been administered in this country and abroad without the production of argyria, it appears that the danger of producing this distressing complication is very slight, probably on account of the chemical state of the silver in the molecule; but it cannot be said that the danger does not exist and I personally have always feared the possibility of this accident and have never given any single patient more than six injections. While silver arsphenamin may be slightly more spirocheticidal than arsphenamin the difference is slight at best and in my opinion it is hardly worth while to assume the chances of producing argyria with silver arsphenamin when equally good therapeutic results can be obtained with arsphenamin and indeed, with some brands of neoarsphenamin.

Kind and Dosage of Drugs in Relation to the Arsenical Dermatoses.—In the first place, it may be stated that all of the skin and mucous membrane lesions described above have been produced by various organic and inorganic compounds of arsenic and are not by any means toxic reactions peculiar to arsphenamin and its substitutes as neoarsphenamin and sulpharsphenamin; cases in illustration are those reported by Brooke and Roberts[88] from arsenical beer poisoning; of those reported by Putman[89] due to the arsenic in wall paper and a recent and striking case of severe exfoliative dermatitis following the administration of sodium cacodylate reported by Pusey.[90] It is not proper, therefore, to designate these reactions as "arsphenamin dermatitis;" rather they are *arsenical dermatoses.*

But unquestionably the various organic arsenicals vary somewhat in the productiveness of these dermatoses; arsphenamin is probably more likely to produce them than neoarsphenamin and sulpharsphenamin may produce more than either being somewhat similar to arsenophenylglycin in this respect. But the important practical point is that these lesions are produced by different arsenical compounds which naturally justifies the conclusion that it is the arsenic which constitutes the most important single factor in their

production. It is not possible, however, at present to work out a relationship between the chemistry of the compounds and the incidence of dermatitis and allied reactions, but as just stated, I believe that arsenic constitutes the toxic factor of most importance; it is practically certain that arsphenamin and its substitutes undergo profound changes after injection, but we do not know anything definite regarding the exact chemistry of these changes in relation to the production of skin lesions.

In a broad and general manner large doses of arsphenamin and its substitutes are more likely to produce these reactions than small doses, but there are striking exceptions in the case of individuals with natural hypersensitiveness to arsenic who react after the administration of small amounts. The same is true in the cases of those individuals who gradually acquire an intolerance during treatment, either in the form of acquired hypersensitiveness to arsenic or as a result of accumulation of arsenic in the tissues and especially those developing skin lesions, among whom the injection of small amounts may result in the production of dermatitis. Dosage, therefore, possesses only a very general relation to the production of these reactions and its influence may not be apparent at all, because it is not so much the amount of arsenic injected as the subsequent fate of the arsenic in the patient as modified by factors peculiar to individual cases.

Unquestionably, however, the arsenical dermatoses are more likely to develop among individuals who have received a number of injections than after the first dose although dermatitis has been reported after single injections. This suggests that in the majority of cases there is an accumulative toxic action probably a result of injury to the liver or kidneys or the acquisition of hypersensitiveness to arsenic, but in either case the fundamental changes occur fairly rapidly; in the series of 23 cases reported by Moore and Keidel for example, all but four occurred before the seventh injection and three occurred after the first.

Of further interest in this connection is whether or not the previous or simultaneous administration of mercury, bismuth and the iodids possess any relation to the production of arsenical dermatoses. Only 5 of the 23 cases reported by Moore and Keidel had taken mercury in conjunction with arsphenamin and they are of the opinion that the administration of mercury bears no relation to the etiology of the reactions; Stokes and Cathcart are of the same opinion. Wechselmann[91] and Eicke[92] and others abroad, however, are of the opinion that the administration of mercury may bear an etiological relationship by injury of the kidneys, resulting in deficient elimination; Schamberg[93] entertains the same belief. Ehrlich was also of the opinion that mercury, by damaging the kidneys, may interfere with the elimination of arsenic and thereby favor the production of toxic reactions and especially of hemorrhagic encephalitis. In my opinion, kidney involvement to the extent of interfering with the elimination of arsenic *may* favor the production of the arsenical dermatoses, although liver dysfunction is probably more important in this connection, but certainly the mere matter of administration of mercury is of little importance because both liver and kidneys may not be involved to the extent of interference with elimination. Strathy, Smith and Hannah[94] in reporting the 58 cases of delayed arsenical poisoning observed in an English war hospital, of which 8 had dermatitis, expressed the opinion that the simultaneous administration of gray oil was a predisposing factor and the histological studies of Lucke and myself, described in Chapter XLVI, on the changes produced by mercury in rats and rabbits, has lead me to the opinion that in some cases, at least, the administration of mercury may bear a relationship to the production of the arsenical dermatoses.

Syphilis and General Pathological States in Relation to the Arsenical Dermatoses.—Of considerable interest and importance in relation to this subject of etiology is whether or not the pathological changes produced in syphilis bear a relation to the production of the arsenical dermatoses. Clinically it is apparent that in the urticarias, erythemas and various papular, vesicular and exfoliative lesions that vascular changes in the skin are most prominent and it is well known that *Spirochæta pallida* brings about injuries of the endothelium of the capillaries which may intensify the vasculotoxic effects of the arsenic. Furthermore, it is possible that syphilis involving the liver and kidneys may interfere with the oxidation and elimination of arsphenamin and its substitutes and thereby throw added burdens of elimination upon the skin resulting in the production of lesions through increased vascular injuries.

The Jarisch-Herxheimer reactions of the skin sometimes observed during the treatment of cases of early syphilis in the secondary stage would appear to be due to a combination of the vascular injuries of syphilis plus the vasculotoxic effects of arsenic in addition to an increased affinity of the drug for the syphilitic exudates, and in these reactions at least there is a very definite etiological relationship between the vascular effects of syphilis and the vascular effects of arsenic.

However, the relationship of syphilis to the incidence of the arsenical dermatoses must not be over-emphasized. In the first place, the arsenical skin lesions may and have occurred in non-syphilitic individuals and the pathological changes of syphilis are not at all essential in their production. At best the most that may be stated is that diseased conditions in general including the pathological changes of chronic syphilis, and especially of the liver and kidneys, *may* favor the production of the arsenical dermatoses. In Moore and Keidel's group two of the severe reactions developed in 1800 cases of syphilis of less than one year duration or one in every 900 patients. Among 7200 late cases there were fifteen reactions or one to every 480 cases. These figures tend to show a higher incidence among cases of late syphilis which happens to correspond to my own experience, but Moore and Keidel state that if the probable statistical error is taken into account, considering the small number of cases of dermatitis, these figures do not show any special tendency for reactions of this group to appear either early or late in the disease. These investigators also observed that dermatitis was about three times more frequent in the white as in the colored race and state that since late vascular syphilis occurs with somewhat greater frequency in colored patients, there is no evidence to show that such vascular changes exert any influence upon the production of the dermatoses.

However, I cannot understand how we may escape from surmising that injuries of the liver and kidneys and especially of the former, by drugs or disease, to the extent of interfering with the metabolism and elimination of arsphenamin and its substitutes, may play a rôle in the etiology of the arsenical dermatoses and especially if it is believed, as I believe, that arsenic itself is the real primary etiological factor. Hoffmann[95] in 1911 maintained that the toxic reactions produced by arsphenamin were due to a perverted metabolism by a damaged liver and Glombitza[96] holds a similar view on the effects of syphilitic hepatitis. More recently Widal and his associates[97] have re-emphasized the importance of liver damage on the basis that a disturbance of the normal "proteopexic" functions of this organ by arsphenamin may be the basis of anaphylactic phenomena.

While it cannot be definitely stated, therefore, that injury to the kidneys, liver and other organs by drugs (arsphenamin, mercury and bismuth) or by disease amounting to an interference with the metabolism and elimination

of the organic arsenical compounds, bears a direct etiological relationship to the arsenical dermatoses, I believe that they *may* and if we regard the toxic skin reactions as due primarily to arsenic, dysfunction of these organs and especially of the liver, becomes a matter of considerable importance.

Bacterial Infection and Bacterial Anaphylaxis in Relation to the Arsenical Dermatoses.—Within recent years considerable attention has been given the possible relationship of bacterial infection to the arsenical dermatoses. It will be remembered in this connection that Wechselmann and others held that bacterial toxins in the water used for preparing solutions of arsphenamin may be responsible for some of the toxic reactions, although the dermatoses were not particularly mentioned in this connection. I do not think, however, that this theory commands much consideration at present although, as stated in Chapter XLVIII, the presence of dissolved bacterial proteins in stale water employed for intravenous injections may produce toxic reactions without any particular cutaneous manifestations.

Milian[98] has recently divided the dermatoses into two general groups on the basis of etiology believing that exfoliative dermatitis is the only skin reaction directly attributable to arsenic, while the others are due to the acute exanthemata as measles or rubella or the lighting up of latent bacterial infection following the temporary general lowering of resistance after the administration of arsphenamin. Moore and Keidel and Stokes and Cathcart, however, do not subscribe to the view that some of these skin lesions are simply coincident attacks of measles or other acute exanthems; for myself it be may stated that I have likewise never seen cases in which this hypothesis was substantiated, but Milian's view that latent bacterial infections may be stirred up by the administration of arsphenamin and its substitutes has been verified and is very important in relation to the etiology of these skin reactions.

Stokes,[99] for example, has studied the relationship of focal bacterial infection to these dermatoses, and especially exfoliative dermatitis, with great care and has shown in a clear and convincing manner that the presence of apical abscesses of the teeth, infected tonsils and other foci may predispose to the production of these reactions and more particularly, that an exacerbation of these or their surgical interference may precipitate a severe and even fatal dermatitis. Stokes and Cathcart have advanced the hypothesis on the basis of these clinical observations, that an allergic instability may result either from the continued absorption of a bacterial protein from a focus of infection or from the sudden liberation of such proteins following a flare-up in the focus due to arsphenamin as suggested by Milian. They also believe that it is possible for sudden sensitization to occur by an acute intercurrent infection. In addition to this state of bacterial allergy, they believe that the liver involved by syphilis or earlier injections of drugs may have its functions (proteopexic?) interfered with and thereby make the body unable to deal with the protein toxic substances from a focus of infection as well as with the arsenical metabolites of arsphenamin and its substitutes. They also suggest that arsphenamin may reduce the efficiency of the suprarenals and thereby produce a deficiency of adrenalin in the blood which destroys the vasomotor balance in the peripheral circulation and permitting a vasodilation. Their idea is, therefore, that patients may become anaphylactic to bacterial proteins from foci of infection; that injury to the liver may favor the production of this anaphylactic state and that injury of the adrenals by arsphenamin may result in vasodilation which permits bacterial proteins in the blood to reach the sensitized tissues and thereby produce anaphylactic shock expressed clinically by the various lesions of the skin. This idea was based upon the

observations of Auer,[11] who had previously shown that if the ears of rabbits sensitized to horse serum were rubbed with xylol to produce congestion at a time when the antigen was present in the blood, that an excessively severe reaction occurred suggesting that as a result of the vascular changes in the ear, an increased amount of antigen was brought to these tissues with the production of a local anaphylactic reaction.

When it is remembered that other forms of anaphylaxis and particularly anaphylaxis to foods among both children and adults is frequently associated clinically with various types of eczema, this hypothesis is deserving of very careful consideration. It is to be regretted, however, that Stokes and Cathcart overlooked conducting skin tests with the proteins of bacteria which could have been recovered in cultures of the focal infections in at least some of their cases; tests of this kind may have yielded additional information.

Moore and Keidel, influenced by these observations, offered an explanation of the mechanism of the arsenical dermatoses on the basis of a fundamental anaphylaxis to some foreign protein including the bacterial proteins as suggested by Stokes, but that the administration of arsphenamin or one of its substitutes produced dermatitis by the vasculotoxic effects of the arsenic which permits the access of protein antigen in the blood to reach the sensitized tissues and produce anaphylactic shocks; these anaphylactic reactions in turn produce greater vasodilation and thereby favor the deposit of arsenic in the skin and bone-marrow where it acts as an irritant. In other words Moore and Keidel believe that bacterial or some other form of anaphylaxis may be a fundamental change; that arsphenamin favors the production of bacterial anaphylactic shocks in the skin and that these in turn by producing vasodilation favor the deposit of arsenic in the skin which acts as an irritant. Both theories, therefore, regard bacterial infection as of fundamental importance in the production of the arsenical dermatoses and I believe that the theory advanced by Moore and Keidal is probably applicable to the majority of cases, since Fordyce, Rosen and Myers[101] and others have found an excess of arsenic in the scales and skin of cases of dermatitis.

Furthermore, the toxic effects of arsphenamin upon the bone-marrow with the blood changes described above undoubtedly tend to reduce resistance to bacterial infection and probably explains in part the occurrence of secondary streptococcus and staphylococcus infections in cases of severe dermatitis which may produce fatal terminations.

Arsenical Hypersensitiveness in Relation to the Dermatoses.—Hypersensitiveness to arsenic has been already discussed in relation to the general toxic manifestations of arsphenamin and its substitutes in Chapter XLVII; the subject is of particular interest, however, in relation to some of the dermatoses and for that reason is deserving of brief but special consideration.

It is well known that some human beings possess a natural hypersensitiveness to such drugs as quinin, cocain, procain and other medicinal substances and it is likely that similar state of natural hypersensitiveness to arsenic and mercury may be encountered. By natural hypersensitiveness I mean the condition of individuals displaying unusual or exaggerated susceptibility who have never before had the compounds administered to them. Whether or not human beings may acquire hypersensitiveness to arsenic by repeated doses, is not certain since the intolerance sometimes displayed after six or more injections of arsphenamin or neoarsphenamin may be due to cumulative toxic effects of arsenic.

But I am personally of the opinion that hypersensitiveness to arsenic may be acquired and especially of the skin. I happen to be well acquainted

with the case reported by Klauder[102] of a physician who developed asthmatic attacks and an erythematous scaly eruption of the fingers with occasional outbreaks of an eczematoid eruption on the face whenever he inhaled minute amounts of the powder of arsphenamin or neoarsphenamin during the opening of ampules or had some of the solutions come in contact with his fingers while preparing or injecting them. When the solutions were prepared by some one else and rubber gloves were worn during the administration, these lesions disappeared.

It is true that the hypersensitiveness in this case could not be passively transferred to guinea-pigs by injections of the patients' serum, but this is almost always the case in allergies to drugs; allergies to protein substances which I designate as true anaphylaxis are more successfully transferred to guinea-pigs by injections of serum, but allergies to non-protein substances as drugs, which I designate as hypersensitiveness, are practically never successfully transferred.

It is rather significant that Klauder's case had received an intracutaneous injection of 0.1 c.c. of either a 1:100 or 1:1000 solution of arsphenamin about eight months before the onset of the eczematous dermatitis and asthma which one naturally surmises may have been the sensitizing dose. As previously stated, Klauder has observed that individuals accidentally injected perivascularly with arsphenamin or neoarsphenamin during intravenous injections are especially prone to develop dermatoses and the incidence of the arsenical dermatoses is particularly high after the administration of sulpharsphenamin which is usually given by subcutaneous or intravenous injection. These observations naturally raise the question whether the skin is especially likely to become sensitized by subcutaneous injections of the organic arsenical compounds.

In Klauder's case the application of 2-per cent. solutions of arsphenamin and neoarsphenamin to abrasions of the skin resulted in positive reactions at the end of about four hours. Similar cutaneous as well as intracutaneous tests, however, conducted in 35 cases of syphilis under arsphenamin and neoarsphenamin treatment, a few of whom had recently recovered from dermatitis exfoliativa, yielded negative results. Stuart and Maynard[103] have tested 26 cases including three who had recovered from dermatitis exfoliativa, by intracutaneous injections of arsphenamin and neoarsphenamin in dilutions ranging from 1:1000 to 1:125,000 with positive reactions in two of the three cases of dermatitis. Moore and Keidel,[104] however, report negative cutaneous tests in cases of dermatitis; intracutaneous tests as advised by Stuart and Maynard were not employed.

These observations naturally suggest that in exceptional cases the arsenical dermatoses may be due to acquired hypersensitiveness to arsenic and whenever severe toxic reactions and especially dermatitis follows the first injection of small doses of either arsphenamin or neoarsphenamin properly administered and without evidences of kidney and liver dysfunction, one can hardly escape surmising that such reactions are due to natural hypersensitiveness to arsenic.

Author's Views on the Etiology of Dermatitis and Allied Reactions.—In my opinion the fundamental and most important etiological factor in the production of these skin and mucous membrane lesions is the effect of arsenic; I do not necessarily mean inorganic arsenic, but rather the effects of the intermediate organic compounds or metabolites or arsphenamin, neoarsphenamin, sulpharsphenamin, etc., although inorganic arsenic as contained in the arsenates and arsenites have been known to produce similar lesions. For example, the effects of arsenic upon the capillaries, described in Chapter

XLVI, are alone sufficient for explaining the simple erythemas and urticarias and its presence in the skin may explain the severer forms of dermatitis as well.

In exceptional instances the dermatoses may be due to natural hypersensitiveness to arsenic and thereby explain the rapid development of the lesions and symptoms after the first injection of a comparatively small dose of arsphenamin or one of its substitutes. Hypersensitiveness, however, is more frequently acquired and in such cases the administration of even small doses, after skin lesions have once appeared, may aggravate the lesions or precipitate a new attack. In some cases of mild dermatitis due to arsphenamin it is possible, however, to administer neoarsphenamin or the reverse without injurious effects; this suggests that hypersensitiveness has been acquired to a definite intermediate arsenical compound rather than to basic arsenic itself. But it would appear that in the majority of cases the skin lesions are due to cumulative toxic effects of arsenic, which may be foretold by various prodromal symptoms as excessive malaise, headache, diarrhea, erythema, etc., because skin tests do not ordinarily indicate the presence of hypersensitiveness and the lesions are aggravated or fresh attacks produced by the administration of any of the medicinal organic arsenical compounds.

Faulty metabolism of the arsenic or delayed elimination is probably responsible for the cumulative toxic effects and these may be due to injury of the most important organs concerned namely, the liver and kidneys, by the chronic pathological changes produced by *Spirochaeta pallida* in some cases, to bacterial or other diseases in others and to the administration of mercury in probably not a few. The skin is known to eliminate arsenic normally after the administration of arsphenamin and its substitutes and with deficient elimination by the liver and kidneys it is reasonable to suppose that more is brought to the skin for elimination where the excess acts as an irritant. In those cases of mild dermatitis due to arsphenamin in whom treatment may be continued with neoarsphenamin without ill effects, it may be that these cumulative toxic effects are not apparent because the latter compound is less toxic and more rapidly metabolized and eliminated than the former.

It is entirely reasonable to expect that the administration of arsphenamin and neoarsphenamin may stir up foci of latent bacterial infection just as they most certainly may stir up latent foci of *Spirochæta pallida;* under these conditions we may well expect in some cases to see the clinical effects of such increased bacterial activity as described by Stokes and especially if the arsenic has produced the bone-marrow and blood changes described by Moore and his colleagues, which still further reduces resistance to infection. Furthermore, there is no reason why we should not accept the hypothesis of Stokes that in some cases there is in addition to the toxic effects of arsenic in the skin the added effects of bacterial anaphylaxis characterized by additional vascular changes as is true in all forms of allergy in human beings, which may result in the still greater deposit of arsenic in the skin as believed by Moore and Keidel. Under these conditions the dermatoses and especially the severer kinds of dermatitis with exfoliation may be regarded as due to the irritant effects of arsenic in the skin alone or in combination with an acute bacterial anaphylaxis plus the elimination of toxic protein substances and a reduction in resistance or immunity to bacterial infection resulting in secondary local or general infections.

But I believe that it is arsenic which is the basis of the mischief. Arsenic is responsible for the primary toxic effects upon the capillaries and the resulting vasodilation and serous exudation shown clinically by various exanthe-

matous, macular and urticarial rashes. It may be likewise responsible for herpes, although in view of the recent investigations of Goodpasture and Teague[105] these lesions may be due to bacterial infection. It is the arsenic of the compounds which may induce a state of hypersensitiveness or accumulate in the various organs and tissues to be brought to the skin in either excessive amounts or in chemical state of enhanced irritating qualities. It is likewise probable that the arsenical substances of arsphenamin and its substitutes are the agents which may stir up latent bacterial infections and produce the toxic effects in the bone-marrow with resulting changes in the blood and reduction in resistance to secondary local or generalized bacterial infections. The mild dermatoses may be due, therefore, to the effects of arsenic alone; the severe dermatoses are due not only to the presence of arsenic in the skin, but in part to the effects of arsenic upon other organs and tissues and especially upon the liver, bone-marrow and foci of bacterial infection.

Prevention and Treatment of Dermatitis and Allied Reactions.—As a general rule, the arsenical skin reactions develop during a course of injections of arsphenamin, neoarsphenamin or one of its substitutes and various prodromal symptoms and signs may give warning of the approach of severe reactions if arsenic therapy is continued. Of these prodromata I have found itching, especially of the palms and soles and sometimes associated with numbness of the fingers, of most significance; some patients exhibit nervousness and irritability, extreme weakness and malaise, excessive diarrhea and headache. Mild and localized urticarial and erythematous rashes may appear; Moore and Keidel state that these do not preclude continuing with arsenic therapy, but I believe it is well to stop for a while all injections of arsenic upon the first appearance of any of these signs and symptoms and that this practice constitutes a very important phase of the prevention of the severe forms of dermatitis. Treatment may be continued with one of the compounds of mercury or bismuth without harm for one or two months and thereby permit the elimination of arsenic from the tissues. But in cases of severe dermatitis of the exfoliating type I believe it is well never to hazard further injections of arsenical compounds but to continue treatment with mercury, bismuth and the iodids. In the less severe forms of the dermatoses arsenical treatment may be resumed after this rest of one or two months, but always with a compound other than that producing the reaction, with small doses and with intervals of one to two weeks between injections until one is sure that ill effects are not being produced. For example, if arsphenamin has produced the reaction treatment may be continued with neoarsphenamin beginning with 0.05 to 0.1 gram.; if produced by sulpharsphenamin treatment may be resumed with arsphenamin or neoarsphenamin in dose of 0.05 to 0.1 gram. etc. But a very careful watch should be maintained for untoward effects and the injections stopped if itching, paresthesia, erythema, urticaria, etc. develop. Otherwise, the doses may be gradually raised by 0.1 gram. until the full dose is being administered. In addition it may be well to make total and differential leukocyte counts of the blood at frequent intervals as advised by Moore and Keidel; leukopemia associated with a reduction in the percentage of polymorphonuclear neutrophils with an increase of eosinophils and of the large mononuclear-transitional cells, or the appearance of many fragile or abnormal leukocytes, are to be considered of serious portent.

It might be worth while in cases of this sort first to employ intradermal tests for determining whether or not intolerance remains before resuming treatment with an arsenical. For this purpose I would suggest the *intra-*

cutaneous injection of 0.1 c.c. of 1:1000 dilutions of the drug which produced the untoward effects and the drug which it is proposed to use. If the reactions are negative forty-eight hours later arsenical treatment may be resumed but always with a different kind of arsenical than that which produced the dermatitis and always with small doses at longer intervals.

The treatment of gingivitis or surgical removal of foci of bacterial infection, and especially of apical abscesses of the teeth and tonsils, may be mentioned in connection with this subject of the prevention of arsenical dermatitis as emphasized by Stokes and his associates. But these precautions apply to the treatment of syphilis in general and will be referred to again in later chapters with more detail. It is well to emphasize here, however, that after signs and symptoms of dermatitis have once appeared such foci should not be disturbed until the danger of acute dermatitis has subsided, since Stokes has recorded instances of acute exacerbations with fatal generalized infections in instances of this kind.

Mild reactions offer no particular difficulties in treatment although the lesions and especially itching may be very annoying. Lassar's paste is excellent for application to herpetic lesions and for the relief of itching and burning of the skin and especially of urticaria, the frequent application of calamine lotion to which is added 5 grains of menthol and the same amount of phenol per ounce, usually affords relief. A brisk saline cathartic is also advisable as well as a simple diet of milk and vegetables. I also administer internally 10 grains of sodium thiosulphate (sodium hyposulphite) three times a day after meals, as this drug was originally advocated by Duhring for relief of urticaria and has since been especially advised for the treatment of arsenical dermatitis. Measures of this sort, along with prompt cessation of the injections of arsenic, are usually sufficient for the treatment of the milder dermatoses during the acute stages. Later, as the skin becomes dry and peals, it may be well to apply an ointment once or twice a day and especially to the soles of the feet where the fissure may be deep and liable to secondary infection; for this purpose one may employ any bland and soothing ointment to which are added 10 grains of phenol and an equal amount of calomel per ounce for the relief of itching and for bactericidal effects.

Severe dermatitis, however, of which dermatitis exfoliativa is the type, requires more vigorous treatment and careful nursing. The patient should be put promptly to bed and every precaution taken to prevent chills. A brisk saline cathartic should be given and daily evacuation of the bowels maintained in order to promote elimination by this route. The diet should be chiefly gruels, milk and milk preparations; meat and eggs should be forbidden. Plenty of water should be given in order to promote diuresis. The skin requires special care. A daily hot or warm bran bath or one containing a handful of washing soda may afford considerable relief from itching and especially when given during the evening hours. Calamin lotion containing phenol and menthol as mentioned above may be applied several times a day or if the skin is hot and dry, a soothing emollient is to be preferred as a mixture composed of 8 grams of gum tragacanth, 100 c.c. of olive oil and 140 c.c. of lime water. Moore and Keidel advise frequent changes of sterile night dresses and sterile sheets to lessen the dangers of infection. Sterile surgical stockings are also an aid and the hands may require bandaging to prevent scratching. McBride and Dennie state that daily exposure to sunlight is of great importance.

The mouth must be attended to with special care and likewise the face and eyes. Two or three drops of 25 per cent. argyrol should be dropped into each eye twice daily followed by boric acid solution. When the edema of the

face is excessive I have applied clothes wet with a saturated solution of magnesium sulphate with success and the same may be applied to other parts of the body with great relief.

Internally it is well to administer 1 gram of sodium thiosulphate (sodium hyposulphate) dissolved in water, three times a day; sodium bicarbonate may also be given internally or an alkaline drink of which the so-called Imperial drink is my favorite.

Ravaut[106] has stated that the oral and intravenous injection of sodium thiosulphate is particularly efficacious and the drug has been endorsed by McBride and Dennie[107] for the treatment of acute and chronic poisonings by arsenic, mercury and bismuth on the assumption that sulphur precipitates this group of metals and that sodium thiosulphate converts them into non-toxic insoluble sulphids and is especially serviceable because of its low toxicity. As stated in Chapter XLIV, Voegtlin and his colleagues have shown experimentally in rats that compounds containing sulphydryl groups (SH) as sodium thioglycollate and thiosalicylic acid reduce the toxicity for both rat and parasites (*Tr. equiperdum*) and they have advanced the theory that the toxicity of the trivalent oxids of arsphenamin, neoarsphenamin and their substitutes which are produced after injection of these drugs, is due to the fact that the arsenic of these are specific poisons for the SH group of glutathione and possibly other SH compounds which may occur in protoplasm. The logic of treating dermatitis with SH compounds would be to neutralize the toxicity of arsenic for the SH compounds of the protoplasm of cells and thereby to relieve the cells of injury; sodium thiosulphate, however, in their experiments, was found to be ineffective. McBride and Dennie maintain that this drug does afford relief and, as stated above, it is their belief that it acts by converting the arsenic in an insoluble sulphide.

One thing is certain and that is the very low toxicity of sodium thiosulphate. White rats can be safely injected intravenously with doses as high as 1 to 2 grams per kilogram of weight which are 50 to 100 times more than administered to human beings by McBride's and Dennie's plan of treatment which has been described as follows: "Given a typical case of arsphenamin dermatitis, the administration is as follows: 0.3 gm. of sodium thiosulphate is given intravenously; the following day, 0.45 gm.; the third day 0.6; the fourth day 0.9 gm.; the sixth day, 1.2 and the eight day, 1.8. This is usually sufficient for the severe case of arsenical dermatitis. Following the first dose, the redness, edema and serous exudate become lessened. The dry, desquamating stage is reached on the fourth to the tenth day. The entire course of the condition is shortened from three to six months to as many weeks."

Favorable results have also been reported by Sutton,[108] Miller,[109] Brigg and Fockoff,[109a] Harrell,[109b] Armuzzi,[109c] and others, but Greenbaum[109d] has observed much better results following the daily intravenous injection of solutions of *thiosinamin* in dose of 3 grains dissolved in 10 c.c. of sterile water. Thiosinamin in this dose is usually well borne but may produce a bitter taste and acid eructations; also digestive disturbances and lassitude fever.[109e] In animals Tyrode[109f] has described severe changes in metabolism with parenchymatous degenerations from relatively small doses, but in my experiments the repeated intravenous administration of the drug to rats and rabbits in dose of 3 to 10 grains (0.2 to 1.0 gm.) per 60 kilograms of weight produced no histological changes in the kidneys, liver or other organs.

Fraser and Duncan[110] have advocated daily intramuscular injections of *contramine* (*intramine*) in dose of 2.5 c.c. of a 1-per cent. emulsion. As many as twelve injections may be given; the local reactions are said to be but mild accompanied by a rise of temperature which subsides the following day.

The therapeutic effects may be enhanced by three or four intravenous injections of collosol iodin in dose of 50 to 100 c.c. French[111] and Rawlins[112] have also found this drug useful in many cases although it has occasionally failed to evert a fatal termination as reported by Fraser.[113] *Afenil* (chlorcalcium-carbamide) has also been advocated for treatment for subcutaneous or intramuscular injection in dose of 0.5 to 1 gram (5 to 10 c.c. of 10 per cent. solution).

Stomatitis if present may yield to treatment with sodium thiosulphate or thiosinamin as described above, but usually requires local measures as well and especially when severe. If smears show excessive numbers of spirochetes and fusiform bacilli it may be well to apply solutions of arsphenamin or neoarsphenamin locally several times a day. These do not appear to intensify the inflammatory reaction, but on the contrary may destroy the spirochetes with clinical improvement. For this local treatment I dissolve 0.2 gm. arsphenamin in 10 c.c. of boiling hot water and add 10 c.c. of glycerin. This mixture gives a 1 per cent. solution of the drug in 50 per cent. glycerin; alkalinization is not necessary. The solution oxidizes (darkens) upon standing, but this change does not reduce its local spirocheticidal activity. In addition it is serviceable to wash out the mouth several times a day with a 1:2000 solution of mercurophen, due care being exercised against swallowing the solution. The metallic tastes left by both arsphenamin and mercurophen can be removed with a final rinsing with cinnamon water.

In severe *aplastic anemia* treatment with sodium thiosulphate or thiosinamin should be given; transfusions with matched blood may be tried, but Moore and Keidel have not observed these to yield beneficial results.

Influence of Dermatitis on the Course of Syphilis and the Wassermann Reaction; "Esophylaxis."—In conclusion mention may be made of the observations of Hoffmann[114] who applied the term "esophylaxis" to a reversal of strongly positive Wassermann reactions to negatives, observed in certain patients after recovery from severe attacks of dermatitis, on the basis that the skin has a defense reaction which protects the internal organs. Buschke and Freymann[115] have also observed that the eczematoid eruptions with pronounced skin changes usually aids in the cure of syphilis with regression of lesions and a disappearance of positive Wassermann reactions. These observers are of the opinion that the skin may produce substances under these conditions destructive for *Spirocheta pallida*.

Bruck[116] has likewise subscribed to this view believing that an attack of dermatitis aids in some way the specific curative effects of arsphenamin and its substitutes just as *x*-ray and light therapy of gummata may aid specific medicinal treatment. Klaas[117] has also reported that in some cases recovering from severe dermatitis the Wassermann reaction is reversed to negative and may show no later symptoms and lesions of syphilis. Gougerot[118] cites several examples favoring this theory of "esophylaxis" and the effects upon the Wassermann reaction may be due to the tissues being more strongly impregnated with the drug than usual, that arsenic is retained in the body, or again that the fever which sometimes accompanies arsenical erythroderma has had a destructive effect on the spirochetes. Lesser,[119] however, disputes these claims and states that dermatitis does not permanently influence either the Wassermann reaction or the subsequent course of syphilis. Parounagian[120] reports a case in which the Wassermann reaction was still positive after the subsidence of severe dermatitis. Benveniste[121] states that the Wassermann reaction may be temporarily reversed to negative during the attack of dermatitis, but that this state lasts only a few months, is followed by positive reactions and that definite clinical symptoms and lesions of syphilis are likely to recur.

My own experience coincides with that of Benveniste; in some cases of severe dermatitis complement-fixation tests conducted according to my new method have yielded negative reactions, but in other cases these serological effects were not observed and in two cases of the first group the negative reactions were later followed by a series of positive reactions. All of these cases happened to be in the chronic stages of syphilis without external lesions so that I was not able to judge the effects of dermatitis upon the syphilitic processes. I believe, however, that it is entirely reasonable to expect some beneficial effects by reason of non-specific protein reactions either as a result of absorption from the skin or as a result of disturbances of protein metabolism by liver dysfunction. The fever and leukocytosis, especially in cases without bone-marrow changes, as well as the stimulation of enzyme and antibody activity, may cause regression of syphilitic lesions with consequent weakening or reversal of the complement-fixation reaction just as these effects in syphilitic cases may be produced by intramuscular injections of sterile milk and other protein agents or the inoculation of paretics with living malarial parasites to produce acute febrile reactions. Furthermore, as stated by Hoffmann[122] and Bloch,[123] in discussing the relation of the skin in general as a means of protection against the entrance of bacteria (exophylaxis) and recovery from infectious diseases, the skin may be a source of some internal secretion or the seat of production of enzymes and antibodies playing an important role in recovery from disease of the internal organs; in some cases of dermatitis it is reasonable to suppose that these functions may be enhanced, while in severe dermatitis they may be reduced with consequent increased chances of bacterial infection and graver prognosis.

Aside from these effects, it is, of course, possible that deficient elimination of arsenic may result in an enhancement of spirochetic destruction which would tend to bring about temporary clinical and serological improvement although there are no reasons for believing that the dermatoses are due to toxic substances from destroyed spirochetes.

At any rate it would appear that in some cases of dermatitis there may be at least temporary improvement in the syphilitic infection in compensation to the patient for a very disagreeable and even dangerous illness, but it is important for the physician to remember that these reactions do not result in spontaneous cures and that specific treatment should be continued with mercury or bismuth in conjunction with the iodids.

Neuritis, Neurorecurrences and Neural Herxheimer Reactions. *Paresthesia.*—During the administration of arsphenamin and its substitutes, some patients complain of numbness of the fingers and soles of the feet. In the hands the numbness is especially noticeable when the arms are stretched and the majority of individuals with these lesions state that the hands and feet feel "asleep." As stated in the preceding section, these symptoms frequently forecaste the development of dermatitis and sometimes accompany itching of the skin and especially of the hands and always indicate the necessity for stopping further injections of arsenical compounds until the symptoms have disappeared. After this has occurred treatment with the arsenicals may be resumed, but safely only with a different kind of compound than that producing the paresthesia, in small ascending doses at longer intervals between injections and with very careful surveillance of the patient.

It is my impression that these symptoms are produced by injections of sulpharsphenamin somewhat more frequently than by arsphenamin and neoarsphenamin. As a general rule, the symptoms develop after a number of injections of large doses have been given, but I have seen several cases develop

after single intramuscular injections of 0.4 gm. sulpharsphenamin and neoarsphenamin.

There is no pain and the reflexes do not appear to be involved. The lesions, however, are apparently those of a mild neuritis due to arsenic. As a general rule, the symptoms entirely disappear within three weeks after cessation of arsenical injections without permanent after effects.

Polyneuritis.—This neuritis is so mild that paresthesia may be the only symptom, but severe cases of polyneuritis are not unknown and especially after the administration of excessively large doses of neoarsphenamin, the symptoms and lesions being exactly similar to those produced by inorganic arsenical compounds. As early as 1912 Duhot[124] described five cases developing two to three weeks after the administration of four or five injections of neoarsphenamin in dose of 1.2 to 1.5 gm. each every two or three days. The patients first complained of pain in the soles and calves associated with dermatitis; later the planter, Achilles and patellar reflexes disappeared, associated with muscular weakness and even paralysis. Similar but less severe symptoms appeared in the hands and arms, but there were no disturbances of sight and hearing or of rectal or bladder functions. At about the same time, Wechselmann[125] stated that arsenical neuritis may follow injections of neoarsphenamin and since then additional cases have been described by Spillmann,[126] Sicard, Hagneman and Kudelski,[127] Solomin,[128] Pürkhauer and Mauss,[129] Bayet,[130] Schamberg and Greenbaum[130a] and others. Beeson[131] has also described a case of polyneuritis due to neoarsphenamin with flaccid paralysis beginning peripherally and extending centripetally, accompanied by muscular atrophy, prodromal pains in the extremities, marked pain in the affected parts on pressure, absence of bladder and rectal disturbances and Babinski's sign and with no pupillary changes.

Neoarsphenamin, therefore, appears to have produced more cases of polyneuritis than arsphenamin, but cases due to the latter have been reported by Variot and Bouquier[132] and by Abadie and his colleagues.

Toxic Amblyopia.—Unquestionably this neuritis is caused by the arsenic of these compounds. It is to be noted, however, that the optic and auditory nerves are not involved by the arsenic of the trivalent compounds, arsphenamin, and neoarsphenamin whereas the arsenic of the pentavalent compounds atoxyl and tryparsamid is especially likely to produce retrobulbar neuritis with transient dimness of vision or permanent amblyopias. Indeed, for this reason atoxyl has largely fallen into disuse as a therapeutic agent. Milian[133] has recorded three cases of visual disturbances following the intravenous administration of neoarsphenamin and believes that the myopia was due to a spasm of the ciliary muscles; he also states that whereas the arsenobenzols have an affinity for the sympathetic system, the oxygen compounds of arsenic (arsenic acid, arsenates) have an affinity for motor nerves, and phenylarsinic compounds (such as atoxyl) for the sensory, optic and auditory nerves.

Pearce[134] has observed cases of amblyopia treated with tryparsamid among patients with moderately or markedly advanced trypanosomiasis of the central nervous system, but not in the early stages of the disease; in a few cases there was permanent impairment of vision. Lorenz and his associates[135] observed dimness of vision in approximately 40 per cent. of their cases of neurosyphilis after four or five doses totalling 5 grams each. In all but two cases of paresis the amblyopia was transient. Moore and his colleagues[136] observed dimness of vision in fourteen patients among 150 cases treated with tryparsamid in doses of 1 to 3 grams at weekly intervals. In ten of these, the visual impairment was slight in degree and cleared up at once when the drug was stopped. In one, a patient whose original lesion

was syphilitic neuroretinitis, there was a slight permanent visual defect; while in three instances, disturbance of vision was severe. All of these fourteen cases had neurosyphilis, and in three there was present preexisting syphilitic disease of the optic nerve. They did not see any cases of amblyopia in early or late syphilis without involvement of the central nervous system, but ascribe the disturbances to arsenical retrobulbar neuritis and believe that, because of the extreme danger of causing amblyopia, the administration of tryparsamid ought to be confined to those classes of syphilitic patients in whom satisfactory therapeutic results cannot be accomplished with any other means.

Neurorecurrences and Neural Herxheimer Reactions.—While the various types of neuritis just described are due to the toxic effects of the arsenic of the medicinal trivalent and pentavalent organic arsenicals, other lesions of nerves and particularly of the cranial nerves may develop which bear an etiological relationship to the administraton of these compounds although they are not expressions of direct toxicity of arsenic on nerves; I refer to those lesions of the cranial nerves which develop after the cessation of treatment or at least late in the course of treatment. They are very probably due to the renewed activity of spirochetes escaping destruction, that is, in cases in which sterilization falls short of being complete. As explained by Erhlich[137] in 1911, the host fails to develop resistance against the spirochetes which survive in isolated foci and which are able to set up an intense lymphoid reaction; if this occurs in nerves or their sheaths symptoms are produced called neuro-recurrences. An analogous reaction has been observed by Bettmann[138] with cutaneous nests of spirochetes producing chancriform papules. Neuro-recurrences, therefore, do not indicate an actual stimulation of spirochetes or a direct action of arsphenamin on syphilitic processes. They occur weeks or months after the interruption of antisyphilitic treatment and are the result of resumed activity of temporarily suppressed spirochetes in patients who have been insufficiently treated and who have not been able to develop resistance. Occasionally a recurrent primary or secondary syphilis will develop at the same time.

Neurorecurrences, therefore, are principally observed in cases of early syphilis receiving insufficient treatment. Recently Gennerich[139] has described 16 cases, twelve of whom showed involvement of the facial or auditory nerves or a combination of these. Zimmermann[140] has recorded 23 cases with the following distribution, likewise showing this predilection for the facial and auditory nerves: optic, 3 cases; oculomotor, 1 case; trochlear, 1 case; facial, 3 cases; auditory, 5 cases; facial and auditory, 10 cases and 1 case each of oculomotor and facial, trigeminus and facial and trigeminus and oculomotor.

Pathological studies of neurorecurrences are not usually possible, but from cases examined by Pirila[141] and Lloyd[142] it would appear that the lesions may be either a diffuse meningovascular process or one limited to one or more focalized lesions.

According to Zimmermann the prophylaxis of such lesions depends on thorough mercurial treatment and it seems immaterial whether mercury is administered during or immediately following a course of injections of arsphenamin or neoarsphenamin. The lesions likewise tend to disappear under treatment, but it is necessary to give treatment with particular care, my practice being to start gradually with ascending doses of mercury or potassium tartrobismuthate before the administration of arsphenamin or one of its substitutes. The purpose of these precautions is to avoid the production of what may be called "neural Herxheimer reactions;" they were not

described by either Jarisch or Herxheimer, but the mechanism of their production appears to be the same as the original Jarisch-Herxheimer reactions which were the accentuation of the exanthems of the secondary stage. The nerves most frequently involved are the third, sixth and eighth cranial nerves. Reactions of this kind are especially likely to develop from the injection of large doses of arsphenamin (0.6 gm.) or neoarsphenamin (0.9 gm.) in cases of latent tertiary syphilis and especially of those with involvement of the oculomotor, auditory and other cranial nerves. Small ascending doses of these compounds are much less likely to produce these accidents as likewise mercury and bismuth; for these reasons the treatment of chronic syphilis should be begun gradually and cautiously rather than by the sudden intravenous injection of the maximum doses of arsphenamin or one of its substitutes. The reactions are not due to the effects of arsenic upon the nerves as is neuritis including amblyopia, but rather to the stimulation of syphilitic processes with sudden accentuation of lymphocytic exudates. Neurorecurrences develop after the cessation of treatment due to a resumption of spirochetic activity of parasites escaping destruction; neural Herxheimer reactions are due to a sudden accentuation of these processes by the administration of antisyphilitic drugs and especially arsenic.

Syphilitic and Arsenical Jaundice.—During the treatment of syphilis with arsphenamin and its substitutes, jaundice may occur and prove an annoying accident and the underlying lesions of the liver may even prove quite serious. It is natural for one at first to suspect the drug or drugs being administered as the cause of this untoward reaction, and especially since it is well established that arsenic administered in any form tends to accumulate in the liver and that it may produce degenerative lesions in the parenchyma of this organ. But it is to be carefully kept in mind that jaundice in syphilis may be due to the syphilitic infection itself or to the combined effects of syphilis and arsenic or indeed, may be entirely coincident and without any relation whatsoever to either syphilis or specific medication.

Classification of Jaundice in Syphilis and in Relation to Treatment.—The etiology of jaundice in syphilis may be, therefore, quite complex and in any given case requires very careful study and consideration from the standpoint of its treatment; the tendency is to jump to the conclusion that jaundice in the syphilitic under treatment is due to the drug or drugs being administered but this is not always true. Indeed I know of no other single symptom requiring more judicious study than jaundice in syphilis because if it is due to *Spirochæta pallida* it is obvious that logical treatment is by antiluetic drugs; however, if it is due to the drugs it is equally obvious that their administration should cease. On the ather hand, jaundice may be due to both syphilis and drugs, but the lesions may be very dissimilar and treatment therefore radically different according to the lesion: for example, it may be due to a combined hepatitis by *Spirochæta pallida* and arsenic in which case the administration of arsenic should cease; or it may be the result of the drug stimulating spirochetes into renewed activity producing what has been called "hepatic Herxheimer" and "hepato-recurrences," in which case antileutic treatment should be continued probably more vigorously than ever unless otherwise contraindicated.

And finally jaundice in the syphilitic may not be due to either the disease or the drugs being administered, but rather to accidental and coincident duodenitis, cholecystitis, cholelithiasis, etc., of other origin; in other words, the physician must exercise due care in guarding against the common error of ascribing all of the lesions and symptoms of disease in the syphilitic to *Spirochæta pallida* or the antiluetic drugs being administered; it is by no means

always easy, however, to differentiate these etiological factors and especially in late syphilis, but an etiological classification aids this important duty and the following has proven quite serviceable:

1. Due alone to syphilis
   - (*a*) In early syphilis (Icterus præcox lueticus)
     - Mild jaundice
       - Duodenitis
       - Hepatitis
       - Cholangitis
       - Pressure on common bile ducts
     - Severe jaundice—acute yellow atrophy
   - (*b*) In late or chronic syphilis
     - Chronic diffuse hepatitis
     - Chronic localized hepatitis (gummata)
     - Chronic perihepatitis
2. Due alone to arsenic
   - (*a*) By producing fatty degeneration, hepatitis and cholangitis
   - (*b*) By producing gastro-enteritis (obstructive jaundice)
3. Due to syphilis and arsenic
   - (*a*) Combined syphilitic and arsenical hepatitis
   - (*b*) Hepatic Jarisch-Herxheimer reactions
   - (*c*) Hepato-recurrence
4. Due neither to syphilis nor to arsenic
   - (*a*) Gastro-duodenitis of bacterial or other origin
   - (*b*) Coincident cholecystitis, cholelithiasis, etc.

Incidence and Etiology of Jaundice in Syphilis.—Jaundice occurring during the primary and secondary stages of syphilis is practically always due to infection with *Spirochæta pallida* and occurs in from 0.2 to about 2 per cent. of cases being somewhat more common in women, who appear to be in general more subject to other gall-tract injuries as cholelithiasis and cholecystitis which may be predisposing factors. As a general rule, the jaundice is of rather sudden onset coincident with the general eruption of syphilis and rapidly disappears under specific medication. This type of jaundice is usually mild and the underlying lesions may be quite diverse; for example, in some cases it appears to have been due to duodenitis, in others to local or diffuse syphilitic hepatitis and cholangitis and in others still to the pressure of enlarged lymph-glands upon the bile ducts. In other words, the mild jaundice of early syphilis is not necessarily an actual hepatitis or cholangitis, but I believe these are the usual lesions. Wile[143] has summarized the literature up to 1917 and it is hardly necessary to devote more space to the subject in this treatise, although I shall refer to it again in Chapter LXXV on the treatment of syphilis of the liver.

The majority of cases of jaundice in early syphilis are mild, but in approximately 10 per cent. of cases the jaundice may be severe and of the acute yellow atrophy type as reported by Gordon[143a] and others, in which the prognosis is very grave; this dreaded complication is, therefore, quite rare at the present time probably not occurring more frequently than once in 1000 to 2000 cases of acute early syphilis insofar as one may judge from the available literature upon the subject. Practically all investigators have agreed that in syphilis this is a true degenerative hepatitis and cholangitis due to *Spirochæta pallida* and its toxins. Acute yellow atrophy is, however, like the mild type of jaundice, more common in women, the proportion being about 5:1 and in some cases has occurred in pregnancy. Of course, one cannot be sure that predisposing factors are always present in these severe cases, but I strongly suspect that such is the case in addition to an unusually heavy infection of the liver with *Spirochæta pallida*.

It cannot be said, however, by any means that the incidence of jaundice in syphilis indicates the percentage of cases in which this organ is invaded and infected by *Spirochæta pallida*. Indeed, the incidence of hepatitic syphilis cannot be expressed at all because it is sure that infection may be present in the majority of cases without jaundice or other obvious symptoms. Neither can the incidence be expressed accurately on the basis of gross necropsy findings, because *Spirochæta pallida* may be present with the production of very small focal or diffuse lesions which cannot be detected with the naked eye. Only very care-

ful histological studies in the future will disclose the true incidence of hepatic syphilis, since Warthin's studies have shown the importance of microscopical examinations of tissues for evidences of syphilitic infection. McCrae[144] states that among 3300 autopsies at the Johns Hopkins Hospital there were 46 of well-marked syphilis of the liver, but in many of these there were no clinical manifestations. Rolleston quotes 64 cases among 11,629 autopsies at St. George's Hospital, London, and Flexner 88 cases among 5088 autopsies at the Philadelphia General Hospital. More recently, McNeil[145] found 64 cases of syphilis of the liver diagnosed during life in 1000 cases of syphilis; in 300 necropsies on syphilitic subjects involvement of the liver was found in 90. It is practically certain that the true incidence of syphilis of the liver is much higher; mild cases do not come to autopsy and most are sufficiently held in check by therapeutic measures to prevent chronic lesions of such character and size as to permit diagnosis during life. Based upon finding such gross changes in the liver as large gummata at necropsy, the incidence of hepatic syphilis in any large series of unselected subjects would appear to be from 0.5 to 2 per cent.; based upon combined macroscopical and microscopical studies as conducted by McNeil in unselected cases, the incidence is about 9 per cent. and combined examinations of this kind in necropsies upon syphilitic subjects has shown an incidence of 30 per cent. in the series reported upon by McNeil which comes closer to expressing the incidence of the infection of the liver with *Spirochæta pallida* in which evidences were discoverable at death.

Space does not permit a detailed description of the acute and chronic lesions of the liver produced by *Spirochæta pallida;* adequate descriptions are to be found in systematic works upon pathology and syphilis. It is, however, quite important for the physician to be acquainted with the signs and symptoms of acute and chronic syphilis of the liver and the gall-tract because the treatment of jaundice in syphilis demands this differentiation into cases due to *Spirochæta pallida* alone, to drugs alone, to a combination of *Spirochæta pallida* and drugs and lastly to extraneous and unrelated causes. In acute syphilitic hepatatis, jaundice may be only one of the signs; enlargement of the liver with tenderness, pain and belching after eating, etc., are usually additional important signs and symptoms. In chronic localized or diffuse syphilitic hepatitis, irregular or nodular enlargement of the liver, jaundice, epigastric pain and hepatic tenderness, ascites and enlargement of the spleen in some cases, symptoms grouped under the obsolete term "dyspepsia" etc., are usually additional signs and symptoms.

Incidence and Etiology of Jaundice Occurring in Cases of Syphilis in Relation to Treatment.—In any discussion of the incidence and etiology of jaundice in cases of syphilis under treatment with the organic arsenical or other medicinal compounds, it should be realized at the outset that in any given case the jaundice may be due to syphilis alone, to some other coincident and extraneous infection or pathological state alone, possibly but not at all probably to the drug alone, or most frequently of all, to various combinations of these circumstances.

Before considering these several conditions it may be stated, however, that the incidence of jaundice in cases of syphilis under treatment is very low; indeed, jaundice constitutes a relatively rare accident or complication although at some periods the incidence may be unusually high and above the average. For example, Stokes and Ruedemann[146] state that 70 cases of jaundice occurred in approximately 5200 cases of syphilis under observation in the Section of Dermatology and Syphilis of the Mayo Clinic from August 1916 to July 1920; this gives a case incidence of about 1.3 per cent. but 64 of these cases occurred between August, 1918, and July, 1920, suggesting to these investigators the possibility and probability that many were due to coincident infections apart from syphilis and the administration of arsphenamin. Bodin[147] has had a similar experience; of 254 cases of syphilis treated with neoarsphenamin between 1912 and 1914, only two or 0.78 per cent. developed jaundice; among 113 cases treated with a different brand during 1919 and 1920, it appeared in two or 1.77 per cent.; while in a third series of 472 cases treated in 1921, jaundice occurred in 34 or 7 per cent. All stages of syphilis were represented, and all soon recovered from the temporary jaundice. Holland[148] had likewise stated that the indidence of jaundice was greatly increased between 1920 and 1923.

In a statistical analysis by Meirowsky covering 225,780 injections of arsphenamin, neoarsphenamin and sodium arsphenamin, jaundice occurred once in each 2000 injections of arsphenamin (0.89 per cent. of cases) and once in every 6000 injections of neoarsphenamin. In 1915 Milian[149] reported 17 cases of jaundice among 800 cases of syphilis under treatment, an incidence of about 2.12 per cent. Five of these cases developed during treatment and twelve after the cessation of treatment constituting hepato-recurrences. Milian states that jaundice is particularly likely to occur during the second half of the first year of the disease.

Harrison[150] has reported the occurrence of jaundice in 0.6 per cent. of cases of syphilis during or subsequent to treatment with arsenical compounds. Morgan,[151] quoting Ravaut, states that in 94,762 injections of arsenical preparations in the treatment of syphilis in the French Army, in which the following preparations were used—novarsenobillon, 37,352, neosalvarsan, 35,836, salvarsan and arsenobillon 9,215, galyl 8,846 and luargol 3,523—there were twenty cases of jaundice which were divided among the various drugs as 7, 8, 1, 2, and 2 respectively. Fenwick, Sweet and Lowe[152] report two fatal cases out of 263 cases of syphilis treated by them. Scott and Pearson[153] state that among 2243 cases of syphilis treated with 13,664 injections of various arsenical preparations there were 39 cases of jaundice giving a case incidence of approximately 1.7 per cent.

Jaundice due to syphilis alone has already been discussed above and not a few observers as Tachan,[154] Lindstedt[155] French[156] MacCormac and Dodds[157] and others have expressed the opinion that jaundice developing in cases of syphilis under treatment is due rather to spirochetic infection of the liver with the production of widespread fatty degeneration and other changes than to the hepatic effects of the drugs.

But others are inclined to hold arsphenamin and its substitutes primarily responsible for the liver injuries. Golay,[158] for example, has reported three cases of jaundice produced by arsphenamin occurring in patients who were not suffering with syphilis and similar cases have been recorded by Pulvermacher,[159] Zimmern[160] and others. As a matter of fact it is frequently impossible to state in cases of syphilis whether the jaundice is due to the disease or some other incidental infection, to the drug or to a combination of these. The effects of antileutic drugs alone upon the livers of normal healthy human beings cannot be accurately determined, because the administration of these in repeated doses is practically confined to individuals with syphilis in whom the liver may be infected with *Spirocheta pallida;* accordingly we must resort to experiments on the lower animals and of these the white rat is best adapted because its diet can be made quite similar to the mixed diet of human beings.

Studies of this kind with arsphenamin and other organic compounds of arsenic have been described in Chapter XLVI. Undoubtedly large repeated doses may cause vascular and degenerative lesions of the parenchyma with some involvement of the bile ducts, but doses comparable to those given human beings on the basis of body weight produce none or but slight and inconspicuous histological changes. I believe it may be stated that the organic and inorganic arsenical compounds are capable of producing changes in the liver by reason of the storage and eliminative functions of this organ, but approximately normal and healthy livers of human beings are probably not injured in the great majority of cases by the usual forms of treatment with arsphenamin and its substitutes; intensive methods of administration are, of course, more likely to produce changes of these kinds than mild courses. But severe invasion and infection of the liver with *Spirochæta pallida* may so interfere with the metabolism and elimination of arsphenamin and its substitutes as to intensify their toxic effects upon the cells; I think the same may be true of other non-syphilitic infections and pathological states of the liver and under these conditions the production of hepatitis and jaundice may be facilitated and hastened. Jaundice, however, may be conceivably due primarily and entirely to arsphenamin and its substitutes by the production of duodenal changes leading to obstruction in the discharge of bile; as previously discussed, the arsenic of these compounds may produce vascular changes in the intestinal mucosa which in exceptional cases may result in the production of obstructive jaundice without involvement of the liver itself in the form of fatty degeneration, hepatitis and cholangitis. Of interest in this connection is the report of Oddo[161] who recently mentioned the frequency with which a history of syphilis is to be elicited in cases of catarrhal jaundice (in 11 out of 25 cases in his practice).

But doubtless, in the majority of instances jaundice occurring in syphilitic individuals under treatment is due to the summation of changes produced by the disease and the drugs if jaundice due to coincident bacterial infection (duodenitis) or other pathological states of the liver like cholelithiasis,

cholecystitis, etc., can be excluded. Syphilis of the liver undoubtedly predisposes to jaundice by interference with the physiological functions of the organ and especially the metabolism, storage and elimination of arsenic just as malarial infection of the liver predisposes to jaundice in cases treated with arsenic as stated by Heinrichsdorff.[162] Brocq[163] believes that arsphenamin and its substitutes may produce vascular and other injuries of the liver and thereby produce localized areas of reduced resistance favoring the localization of spirochetes which in turn may still further reduce the tolerance of the organ for arsenic and thereby set up a vicious cycle intimately involving the effects of infection and drug.

As stated in Chapter XLVI, it would appear that hepatic injuries following the administration of arsphenamin and its substitutes are caused by the arsenic of these compounds rather than by the benzene group of some non arsenical impurity. The liver is known to be an important storehouse of arsenic and in any case of fatal jaundice in which an excess of arsenic is not found in the bile or liver at necropsy one is justified is suspecting that the hepatitis has been caused by some kind of infection rather than by the drug administered.

It may be that the combined administration of mercury may aid in intensifying the hepatic effects of the arsenic of arsphenamin and its substitutes probably by a further interference with elimination by the production of nephritis, as indicated by the high incidence of jaundice (47 cases) in a series of 58 cases of delayed poisoning due to arsphenamin and mercury reported by Strathy, Smith and Hannah;[164] Lynch and Hoge[165] regard the concomitant administration of mercury as an important etiological factor in the fatal cases reported by them on the basis that faulty elimination intensifies the toxic action of arsenic on the liver. Foulerton,[166] commenting on his series of animal experiments, offers another explanation to the effect that mercury may exert a direct toxic action upon the liver already impaired by the toxic action of arsenic, but Wile, Stokes and Ruedemann, Pearson and Scott, previously referred to, have expressed the opinion that the administration of mercury has had no influence in their cases and my own more limited experience has been similar.

Jaundice, therefore, may be the result of a combined hepatitis and cholangitis due to *Spirochæta pallida* and arsenic. In some cases the syphilitic infection alone of the liver may produce no symptoms, but when arsphenamin or one of its substitutes is given, the lesions may be intensified constituting what has been termed as the "*hepatic Herxheimer reaction*" because the condition bears an analogy to the exacerbation of the skin lesions of the secondary stage of syphilis as a result of treatment as originally described by Herxheimer. Of the 39 cases of jaundice reported by Scott and Pearson, six were believed to be due to an effect of this kind in which they were of the opinion that the liver was probably swarming with spirochetes followed by the liberation of toxins following an injection of arsphenamin which produced degenerative lesions.

In other instances it may be that the administration of repeated doses of arsphenamin or neoarsphenamin provoke or stimulate latent spirochetic infection of the liver in a manner similar to the production of the provocative Wassermann reaction or as intercurrent infections, trauma, etc., may stimulate foci of latent spirochetes, and produce a form of jaundice due to the action of both parasites and drug, which is also sometimes spoken of as a "hepatic Herxheimer reaction." Cases of this kind, however, are more likely to fall into the group designated as "*hepato-recurrences*" or *hepato-recidives*" in which jaundice appears several weeks after the cessation of

treatment. In such cases it is believed that the drug has stimulated latent spirochetes into renewed activity with the production of an active syphilitic hepatitis and in a manner analogous to the production of active lesions of the optic nerve or other parts of the central nervous system when antileutic treatment is begun suddenly and vigorously in cases of chronic syphilis. Fabry and Wolff[167] and others have described cases of this kind and in the treatment of chronic latent syphilis of the liver, the administration of repeated large doses of arsphenamin or one of its substitutes may produce temporarily active lesions in this manner. Or in cases of mild syphilitic hepatitis without jaundice the functional capacity of the liver may be still further reduced by repeated injections of arsenic so that the cells cannot cope with the added toxicity of the arsenical compounds and severer lesions with jaundice result. Scott and Pearson reported 11 cases of this type in their series.

What appears to happen still more frequently is that the liver may be only very lightly infected with *Spirochæta pallida*, or may be free of this infection but have its functional capacity lowered by alcoholism or some other pathological state in which the added strain of repeated injections of arsenical compounds may result in the production of hepatitis and cholangitis with jaundice and the usual accompanying symptoms. Scott and Pearson classified 22 of the 39 cases in their series in this category. And finally, the fact that jaundice in syphilitic patients under treatment may not be due either to syphilis or the treatment is deserving of special consideration in view of the excellent investigations of Stokes and Ruedemann previously mentioned. From August, 1918 to July, 1920, the incidence in their experience suddenly increased over 1000 per cent. and their studies on these cases disclosed strong circumstantial evidence to the effect that an infectious agent, possibly associated with epidemic respiratory infections, was the exciting cause. Forty-one per cent. of their patients had coryza, tonsillitis, pharyngitis, influenza, etc., intimately associated with the prodromal symptoms or actual appearance of the jaundice and symptoms suggestive of systemic infection, with lassitude, arthritis and myalgia, backache, diarrhea or constipation, etc., usually preceded by several days or weeks the onset of the jaundice and other hepatic symptoms. Fifty-nine per cent. of their cases were associated with epidemics of colds and influenza and a total of as high as 73 per cent. yielded some contributory evidence of a possible infectious factor in the etiology of the jaundice. Stokes and Ruedemann have very properly stated the possibility of this type of jaundice masquerading as syphilitic or arsenical hepatitis with undue suspicion, perhaps, cast upon modern methods of treatment. This is especially true when no arsenic is to be found in the urine nor in the liver in necropsied cases. They admit that arsenic may be a predisposing factor, but that the exciting agent is as yet an unidentified infectious agent distributed by the blood and sometimes associated with gastro-intestinal lesions; Holland has likewise recently stated that in his opinion jaundice in cases of syphilis under treatment may be due to the fact that the arsenic produces gastro-duodenitis with ascending bacterial infection of the liver. Hallam[168] thinks that an infection resembling Weil's disease (spirochetosis icterohemorrhagica) should be considered as a possible etiological factor and the occurrence of jaundice among his syphilitic patients under treatment almost as an epidemic in 1917–1918 lends color to the suggestion, especially since it was proved that no particular batch of drug was responsible. This possibility is discussed also by Silbergleit and Fockler.[169]

Liver Functional Tests in Relation to Syphilitic and Arsenical Jaundice.—Since syphilitic hepatitis may not be suspected clinically until jaundice and its accompanying symptoms are produced, considerable interest is attached

to the possibility of developing reliable tests for the early detection of incipient dysfunction and jaundice. A reliable and clinically applicable test of this kind would prove of considerable value in the treatment of those cases of syphilis in whom hepatic involvement was suspected. In cases of marked syphilitic hepatitis, for example, preference in the selection of an antileutic drug would be limited to mercury and bismuth or, if one of the organic arsenical compounds were selected, extra caution would be indicated in dosage and intervals of injection in order to minimize or prevent the development of hepatitis and jaundice. From the standpoint of possible value in the diagnosis of syphilitic and arsenical hepatitis, these tests are, therefore, worthy of consideration in relation to the prevention of hepatic injuries and jaundice in relation to the treatment of syphilis.

Probably the best known of these methods is the *phenoltetrachlorphthalein test* originally developed by Rountree, Hurvitz and Bloomfield;[170] the return of the dye was determined by examination of the feces, but many discrepancies were noted by various investigators and since then the technic has been considerably modified. McNeil[171] has advised the collection of the dye through the duodenal tube and Aaron, Beck and Schneider,[172] Piersol and Bockus[173] Friedenwald and Gantt[174] and others have found this modification quite satisfactory. As shown by Wilhelm[174a] the duodenal lavage alone may be of value in the treatment of the jaundice.

Hoxie,[175] however, has found the results obtained by methods of this kind too irregular for reliance and more recently Rosenthal,[176] Rosenfield and Schneiders,[177] and Greenbaum and Brown[178] have advocated the withdrawal of blood at intervals after the injection of dye for the purpose of estimating the rate of its disappearance. This method consists in the removal of about 10 c.c. of blood for a control followed immediately by the intravenous injection of the dye in dose of approximately 0.005 gm. per kilogram of weight. Abel and Rountree[179] state that the dye in the dose recommended is non-toxic, yet Greenbaum and Brown observed occasional untoward effects in the nature of burning pain along the vein if injected too rapidly, late thrombosis, chills, faintness, sweats, and pain in the hepatic region. According to Rosenthal, a normally functioning liver will remove from the blood all but 3 to 7 per cent. of the dye in fifteen minutes after injection; in one hour, removal is complete. Recently Rosenthal[180] has shown experimentally in rabbits that the test can be detected following the removal of approximately 12 per cent. of the total liver substance of these animals.

Greenbaum and Brown found that in 70 to 75 per cent. of syphilitic individuals receiving from 1 to 124 intravenous injections of neoarsphenamin, that the results were normal. This indicates in a general way that neoarsphenamin as ordinarily administered does not produce sufficient disturbance of liver function to interfere with the elimination of this dye. Tests conducted with patients who developed jaundice showed that a more or less permanent degree of dysfunction followed clinical recovery.

Functional tests have also been based upon estimations of *urobilinogen* in the blood by Kahn,[181] for *hematoporphyrin* by Cavina,[182] the rate of elimination of *rose-bengal* (tetra-iodotetrabrom-fluorescene) by Delprat,[183] etc. But most attention has been given qualitative and quantitative tests for *bilirubin* in the blood.

This substance is a transformation product of hemoglobin and a great deal of discussion and an enormous literature have been devoted to the question whether or not it may be produced in tissues other than the liver. In 1886 Minkowski and Naunyn[184] reported a series of experiments with ducks and geese which were at once widely accepted as proof that there could be no formation of bilirubin from circulating hemoglobin without

the participation of the liver. In 1913 NcNee[185] reported essentially similar results observed with experiments on geese and stated that the pigment was a product of phagocytosis by the Kupffer cells of the liver and that it was not produced in animals from which the liver was extirpated except in very small amounts by similar cells in the spleen and bone marrow. Whipple and Hooper,[186] however, working independently of McNee but employing dogs, arrived at opposite conclusions and state that the liver is not necessary for the formation of the bile pigment from circulating hemoglobin. More recently, however, Rich[187] after repeating these and additional experiments arrived at the conclusion that the liver is necessary for the transformation of circulating hemoglobin into bilirubin.

The origin of bilirubin, therefore, still requires investigation but it is well established that small amounts are to be found in the blood of normal healthy human beings as 0.028 gm. or less per 1000 c.c. of blood and that it is increased in various diseases of the liver. Chargin and Orgel,[188] employing the qualitative method of Sunde[189] and the quantitative method of Meulengracht,[190] examined the blood serums and urines of 82 syphilitic cases under arsenical medication and observed that an increase of the bilirubin of the blood occurred in jaundice and served as a danger signal of its approach. Strauss and Buerkmann,[191] Wechselmann and Hohorst,[192] and Schneider[193] have also found that a disturbance of the liver by syphilis or drugs was accompanied or foreshadowed by bilirubinemia. Bernheim[194] has more recently described a method, for determining bilirubin in the blood which expresses the results in what is termed as the "icterus index," the technic being a modification of the Meulengracht method. Gerrard[194a] and Schamberg and Brown[195] have employed Van den Bergh's method[196] with success and this technic would appear to be widely employed. Bailey and MacKay[197] in a study of the blood and urine of 25 cases of jaundice following combined arsenical and mercurial treatment for syphilis in addition to 15 control cases, observed bile pigments in the urine of patients clinically jaundiced and showing bilirubinemia. An increase of urobilinogen was also noted and the oxidation of urobilinogen to urobilin was greatly reduced. Quantitative estimations of the blood for sugar, creatinin, uric acid and urea nitrogen yielded nothing of particular value although in the jaundiced cases there was an *increase of cholesterol* and Bailey and MacKay believe that its routine estimation may be of value in detecting the onset of liver injury in patients under treament since it is increased early and persists after other clinical signs have disappeared. Studies by Desaux and his colleagues[198] with the urine in cases of arsenical jaundice of the biliary acids, urobilin, urobilinogen, azoturic ratio, Arthus-Maillard's and Lanzenberg's coefficients of ureogenic imperfection, as well as of the residual nitrogen of the serum and its ratio to the total non-protein nitrogen, have indicated that hepatic disorders are due not to syphilis or the administration of arsphenamin but to such factors as alcohol, food deficiencies (especially of fats) or concomitant infections.

Finally mention may be made of the so-called *hemoclastic crisis test* devised by Widal, Abrami and Lancovesco[199] for determining the albumosestoring power of the liver as a test of its function. This is based upon the well known fact that after the ingestion of food there is usually an increase of leukocytes present in the blood. Widal and his colleagues observed that after milk has been given to patients with liver lesions, the usual leukocytosis does not occur, a decrease in the number of leukocytes usually being found. The phenomenon has been explained on the basis that the liver being unable to store up albumose the circulation is overcharged with the production of anaphylactic shock.

Normally in adults a mild degree of leukocytosis develops, but in liver dysfunction a leukopenia (digestion hemoclasis) may be observed in which the cells are 200 to several thousand less per cubic millimeter of blood than in the preliminary count. The test is not applicable to children. According to Widal and Abrami in almost 50 per cent. of their 432 cases, the crisis was over less than one hour after the ingestion of the milk. Einhorn[200] states, however, that in a number of cases of severe disease of the liver, the test has not helped to discover an insufficient action of this organ as in most cases there was a distinct digestive leukocytosis present, as in normal persons.

Practical Value of Liver Function Tests.—It is not yet possible to express an accurate opinion of the practical value of these various tests as aids in arriving at an estimate of the possible injury of the liver in syphilis or of other pathological states, by arsphenamin and its substitutes, etc. I believe, however, that they are worthy of serious consideration in cases of chronic active or latent syphilis in whom the presence of an icteric tinge of the mucous membranes or skin, gastro-intestinal symptoms, etc., lead to the suspicion of hepatic disorders and functional insufficiency. In cases of this kind evidence of dysfunction should lead to particular care in the choice of antileutic drugs and their administration and especially of the organic arsenicals, neoarsphenamin being less hepatotoxic than

arsphenamin. For the purpose of aiding in the diagnosis of such cases my preference is for the quantitative bilirubin test of the blood and the blood phenoltetrachlorphthalein test. Conducting the latter by duodenal drainage is quite a severe ordeal for most persons, although it is my preference when I believe something is to be gained in the way of bacteriological and cytological examinations of the bile by Lyon's methods as well as the possible therapeutic effects of the drainage. With slight modifications in the method of Piersol and Bockus described above it is possible to secure these additional data and effects.

Treatment of Syphilitic and Arsenical Jaundice.—It is obvious that the treatment to be given syphilitic persons with jaundice depends to some extent upon the cause of the conditions and an effort should be made to determine this as accurately as possible in each case.

The first question arising for consideration is whether or not specific medication should be started or continued, if already started; probably in the majority of cases of jaundice outside of those developing in the primary and secondary stages of syphilis, most physicians immediately stop the administration of antiluetic drugs but this may not be indicated in all cases.

Jaundice occurring in the primary and secondary stages of syphilis before any or but a small amount of treatment has been given, is usually so obviously due to spirochetic infection that one does not hesitate to administer arsphenamin or neoarsphenamin as a therapeutic measure; indeed, in severe jaundice of this kind (icterus gravis syphiliticus) the only hope for recovery is based upon intensive treatment with arsphenamin, bismuth or mercury as indicated by the recoveries of individual cases reported by Duhot,[201] Umber,[202] and others.

In those cases of *early* syphilis in whom jaundice appears after the first dose or two of arsphenamin or neoarsphenamin and regarded as hepatic Herxheimer reactions, specific treatment may continue, but if arsphenamin or neoarsphenamin is given it is well to reduce the dose and increase the intervals of injection or better still, administer potassium tartrobismuthate which is much less toxic for the liver and ranks next in spirocheticidal activity.

In those cases of late syphilis in whom jaundice appears several weeks after the cessation of treatment indicating the presence of a hepatorecurrence, it is well to interrupt specific medication for a month and then resume treatment, but in view of the fact that one cannot be sure that the hepatitis is not in part due to arsenic, it is my practice to administer ten or twelve doses of potassium tartrobismuthate by intramuscular injection in amounts of 0.1 or 0.2 gm. every four or five days along with small daily doses of potassium iodid by mouth. I think bismuth is to be preferred to mercury in cases of this kind because it is less irritating to the kidneys.

In the larger group of cases in which jaundice develops after five or more injections of arsphenamin or neoarsphenamin and in which we therefore suspect an arsenical hepatitis in addition to syphilitic infection, it is well to stop all specific medication for a month or six weeks at least. Milian and others are so confident that the jaundice is syphilitic, that they continue to administer arsphenamin or neoarsphenamin in many of these cases; but I must confess for my part a generous degree of temerity in following this practice. When I have reason to suspect that syphilis is very likely exerting an active rôle, I administer potassium tartrobismuthate by intramuscular injection in doses of 0.1 gm., but not usually until the patient has had a complete rest for at least one month. When treatment with the arsenicals is finally resumed, the doses should be small (0.1 to 0.2 gm.) and cautiously increased.

When jaundice is due to syphilis, it is clear, therefore, that active specific medication should be given and preferably by the administration of arsphenamin or neoarsphenamin for their prompt spirocheticidal effects. When a less active specific medication is desired and especially in cases to whom arsenical compounds have already been given, preference is to be given to bismuth or some form of mercury. In these cases in whom the jaundice is due to gastro-enteritis (obstructive jaundice) specific medication may cease altogether for at least a month. In those cases in whom the jaundice is believed to be due to arsenical hepatitis entirely or in large part, specific medication should be stopped and measures taken to afford relief from further damage by arsenic.

For this purpose, sodium thiosulphate may be administered orally and by intravenous injection in the same manner as described for the treatment of arsenical dermatitis. This compound is believed by Dennie and McBride to convert the arsenic into a sulphid, which is comparatively non-toxic and non-irritating. I have seen better results follow the intravenous injection of 3 grains of thiosinamin dissolved in 10 c.c. of sterile water every two or three days for several doses. Fraser and Duncan,[203] Scott and Pearson, French and others report good results following intramuscular injections of contramine (intramine-diortho-diamino-thio-benzene) in dose of 2.5 to 3 c.c. every three or four days for three to twelve doses as required. It is believed to act as a reducing agent and is said to act quickly. It usually produces some pain and stiffness and a slight rise of temperature sometimes follows.

Of course, if the jaundice is due to some intercurrent infection and especially to the presence of acute duodenitis, saline laxatives and other appropriate measures are indicated. Certainly it is not well to administer either sodium thiosulphate, thiosinamin or intramine unless there are reasons for believing that the jaundice is due solely or in part to the effects of arsenic.

General treatment applicable to practically all cases consists of the following: (*a*) rest in bed; (*b*) mild laxatives; (*c*) carbohydrate diet which increases the resistance of the liver; no fats and little protein, but milk may be given freely as likewise plenty of water and especially alkaline waters.

Accidental Perivascular Injections of Arsphenamin and Neoarsphenamin. Although intramuscular injections of arsphenamin and neoarsphenamin exert slightly greater therapeutic effects than intravenous injections, yet this route of administration produces so much tissue reaction, necrosis, pain and disability when full-sized doses are injected that it is only employed as present in exceptional cases, although the intramuscular injection of small amounts to children is feasible because the reactions are not excessive since the amounts injected are small.

Sometimes, however, solutions of arsphenamin and neoarsphenamin are accidentally injected into the tissues of the arm during attempts to administer them by intravenous injection. As a general rule, the occurrence of severe sharp pain and the production of a swelling about the site of puncture give warning, so that the injection may be stopped before a great deal has been injected; but when neoarsphenamin is being administered in a concentrated solution with a syringe, a few drops in the perivascular tissues suffices for the production of a very painful reaction. Sometimes the needle transfixes the vein so that a portion of the solution is injected intravenously and a small amount beneath the vein where the swelling cannot be as well seen and detected as in superficial injections. The severest reactions I have ever seen were due to the injection of very concentrated solutions of neoarsphenamin, as 0.9 gm. in 1 to 3 c.c. of water, into the perivascular tissues, the physicians believing the needles were in the veins and giving the injections so

rapidly that all were injected perivascularly before the mistakes were discovered by the development of excrutiating pains.

Symptoms and Tissue Changes.—If only a few drops of solutions of arsphenamin or neoarsphenamin have been injected perivascularly the patient complains of sharp pain followed by dull aching, which persists for several hours to several days depending upon the amount of drug injected. The tissues swell rapidly, the tumor possessing a peculiar hard or doughy consistency, rather sharply outlined with reddened skin. This swelling usually persists for many days and even weeks and months before it is gradually absorbed, the patient being partially disabled for most of this time as the result of pain upon flexion of the arm.

If larger amounts of drug are injected the pain is excrutiating and may radiate if the internal or external cutaneous nerves are involved. This sharp pain sometimes persists for several days along with a great deal of edematous swelling of the tissues including the skin. In a few days necrosis may occur with the ultimate breaking down of the tissues. I have seen cases in which portions of the capsule of the elbow joint were exposed by liquefaction necrosis of the tissues.

The chief tissue changes are muscle necrosis and leukocytic infiltration. The infiltrated muscle fibres become brassy, swell, loose striations and may ultimately liquefy. The capillaries are engorged with blood and interstitial hemorrhages may occur. As a general rule the leukocytes are unable to penetrate to the necrotic muscle but gather at the periphery which accounts for the rather sharp definition of the swellings. Absorption is delayed which probably explains the rather long duration of the tumefactions and their slow resolution. Ultimately fibrous tissue is produced, but without danger of ankylosis or disability unless a very severe necrosis has occurred when the possibility of partial ankylosis is not to be overlooked.

Treatment.—In the great majority of cases only a few drops of solution are injected perivascularly before the accident is discovered. The injection should be stopped immediately and the needle withdrawn. Sometimes a portion of the injected solution can be gently massaged out of the needle puncture of the skin. Wet compresses of a cold saturated solution of magnesium sulphate in water should be applied and the dressings kept moist for at least twenty-four to forty-eight hours or longer depending upon the individual circumstances. An ice bag may be laid over the dressings for the comfort derived and to retard swelling of the tissues. Sometimes hot solutions of magnesium sulphate give more relief than cold solutions and either may be employed.

Dennie recommends infiltration of the involved area with 2 c.c. of a 10-per cent. solution of sodium thiosulphate followed immediately by hot packs of a 5-per cent. solution of the same drug for several hours. If in spite of this treatment the severe infiltration still persists, he advises multiple stab punctures with applications of the hot solution. Dietel[204] has recently recommended injecting 10 c.c. of sterile saline solution into the site of the infiltration and surrounding tissues to dilute the arsphenamin, hasten its absorption and reduce irritation.

If large amounts of solution have been injected and especially a syringeful of a concentrated solution of neoarsphenamin, I believe it is well to incise the area as soon as possible under local or general anesthesia and gently massage out as much of the solution as possible. Due care must be exercised and especially of the internal and external cutaneous nerves. Hot solutions should now be applied either of 5-per cent. sodium thiosulphate in water or 1:3000 mercuric chlorid in hypertonic (10-per cent.) saline to reverse

osmosis as much as possible and to guard against bacterial infection and especially since the wound and sloughing tissues heal very slowly and are readily infected.

Reactions Produced by Intraspinal Injections.—In conclusion a few lines may be written of the cause and treatment of reactions following various methods of intraspinal therapy in neurosyphilis. In my experience the Swift-Ellis method, as described in Chapter LXII, is least likely to produce reactions, although some irritation of the lower cord with shooting pains in the legs may occur and render the patient very uncomfortable for a few hours at least and especially if an acute reaction of fever, chilliness, nausea and vomiting have followed the intravenous injection of the arsphenamin. Whenever I suspect that such a general reaction may occur, it is my custom to substitute an intravenous injection of 0.9 gm. of neoarsphenamin for the 0.6 gm. dose of arsphenamin, but otherwise proceed exactly as described. In my own method neoarsphenamin is now used exclusively in order to spare the patient the possible discomfort of a general reaction.

When arsphenamin or neoarsphenamin are added to serum or spinal fluid and injected intraspinally there is always more chances for lower cord irritation than when serum alone is injected as in the Swift-Ellis method. But by diluting the serum and drug with the patient's own spinal fluid and injecting very slowly by gravity, the degree of pain and discomfort can be greatly reduced and indeed, almost entirely prevented except for the soreness due to the puncture itself.

As a general rule, a feeling of discomfort with slight headache follows intraspinal injections; shooting pains in the legs are not infrequent due to the puncture or pressure, but these generally pass off rather quickly although in some cases morphin is required for relief. Fever and chilliness may develop; nausea and vomiting are not uncommon. Profuse perspiration may also occur, due more to nervousness than the drug, as is likewise the nausea.

By anesthesizing the skin, using a small bore needle (No. 19) and injecting slowly and cautiously, all of the discomfort and pain can be so greatly reduced that most patients do not hesitate or refuse a series of injections at intervals of two to three weeks.

In some instances, however, the ill or untoward effects are more serious and especially in tabes dorsalis. I have seen several cases of this type of neurosyphilis in which intraspinal treatments by the Swift-Ellis method have initiated gastric crises as well as loss of bladder and rectal control. It is my opinion that intraspinal therapy has definite risks and that this treatment should not be given except to selected cases in which thorough intravenous treatment with the arsenicals combined with intramuscular injections of bismuth and mercury by inunction have failed to arrest the progress of the disease. This phase of the subject is discussed, however, with more detail in Chapter LXXVI. The cause of untoward effects from intraspinal injections are probably due in part to disturbances in pressure and the choroid flexus, as well as direct irritation of the meninges and posterior roots of the nerves. In some instances serious respiratory and cardiac disturbances have developed during or immediately after injections and especially rapid injections with a syringe. Even sterile plain serum will irritate the meninges and produce congestion with serous and leukocytic exudations. Recently Kiely[205] has described a severe and fatal reaction due to the sodium citrate employed for the prevention of the coagulation of the blood in my method; I have never observed unusually severe reactions with this method probably due to the fact that I have been more fortunate in the sodium citrate employed but for over a year I have been using but one quarter the amount originally

advised with satisfactory results, the technic being described in Chapter LXII.

The treatment of reactions following intraspinal administrations is generally symptomatic. For those symptoms due to intravenous injections, treatment has already been described. For the shooting pains in the legs nothing much can be done except the hypodermic injection of morphin for severe pains. Of course the patient should be kept in bed for at least twenty-four hours; it is advisable to elevate the foot for an hour or two at least. An ice cap may be applied to the head if headache is complained of. In persistent headache large doses of sodium chlorid may be given internally for the purpose of reducing intraspinal pressure. If retention of urine occurs catherization is required until function is restored.

CHAPTER LII

PHARMACOLOGY OF MERCURY IN RELATION TO METHODS OF ADMINISTRATION AND THE TREATMENT OF SYPHILIS

Although mercury is probably the most ancient of present-day medicaments for various ailments and diseases, and has been employed in the treatment of syphilis alone for more than five centuries, our exact knowledge of its pharmacology and especially the mechanism of its absorption and curative activity in this disease is quite incomplete. It may be said, therefore, that the use of mercury in the treatment of syphilis is still largely on an empiric basis. Within recent years however, the investigations of Wile and Elliott, Cole, Guttman and others in this country, and of Lomholt abroad, have contributed very materially to our exact knowledge of the amounts of mercury absorbed, retained and eliminated in relation to different routes of administration, but we are unable to corelate the results with animal tests

for curative activity which have proven so helpful in elucidating the subjects of the mechanism of absorption and curative activity of the organic arsenical compounds, because mercurial compounds are almost without demonstrable trypanocidal activity even in maximum tolerated doses and of relatively feeble spirocheticidal activity in experimental infections.

Absorption and Elimination of Mercury Administered by Ingestion. Absorption from the alimentary canal may be first considered, especially since the administration of such soluble compounds as mercuric chlorid and the yellow iodid (protiodid of mercury) are so commonly employed during the treatment of some cases of syphilis; furthermore, when mercury is administered by the methods of fumigation, inhalation and inunction, a portion is probably swallowed in the saliva after condensation of the vapors in the mouth and upper respiratory tract. Moreover, since mercury is eliminated in the bile and possibly by excretion by the glands of the intestinal mucosa after administration by all methods, it is entirely likely that a portion is re-absorbed before passage in the feces, accounting in part, at least, for the very long periods of elimination commonly observed after the administration of mercurial compounds. As stated by Fournier, the administration of mercuric chlorid and the protiodid constitutes the most practical method of administration when mercury is to be given over long periods of time.

A large number of mercurial compounds have been advocated for oral administration and the older literature is full of numerous potions and special formulas. In the first place, it may be stated that preference is always given the soluble preparations. Metallic mercury is absorbed so slowly that it is apt to be passed before appreciable amounts have become oxidized and converted into soluble compounds or before sufficient amounts may be volatilized and directly absorbed through the intestinal mucosa. Calomel, however, may be quite readily absorbed presumably after being broken down by the alkaline intestinal juices into metallic mercury and yellow mercuric oxid, the latter slowly dissolving in the intestinal contents; whether or not mercuric chlorid is produced under these conditions is still undecided. In this connection it may be stated that Beinhauer[1] found, by analysis of the urine of patients according to the method of Elliott,[2] that excretion of mercury began from six to twelve hours after the ingestion of ¼ to 2 grains of calomel in doses of ¼ grain every 15 minutes. The rate of excretion was the same for large and small doses and the investigation has proved of interest as showing how rapidly this compound may be absorbed. Lomholt[3] states that a rapid saturation of the body by mercury may be secured by the oral administration of 0.5 gm. (about 7 grains) of calomel; Guttman has found that metallic mercury triturated into small globules in food and fed to guinea-pigs results in absorption and the production of toxic tissue changes, whereas, when given in mass, there may be little or no absorption and no toxic effects.

As compared with administration by inunction, inhalation and injection, absorption from the alimentary canal is much less active; Lomholt states that in a few examinations of the urine made by him the degree of absorption, as judged by the degree of elimination, was very small; details of his experiments were not published. Clinical experience has shown quite conclusively, however, that when mercuric chlorid, the protiodid and other soluble compounds are administered orally in the doses advised by Fournier, considerable amounts are absorbed as indicated not only by such toxic effects as stomatitis and renal irritation, but likewise by curative improvement of syphilitic lesions. Of course, the production of local irritive effects, as "sublimate gastralgia," colic and diarrhea, is not acceptable as evidence of absorption, and the catharsis may indeed materially interfere with absorption by increas-

ing peristalsis and exudation from the intestinal mucosa unless controlled by opium. Nothing is definitely known of the rate of absorbability of different compounds of mercury from the gastro-intestinal canal. Apparently, solubility bears no important relation to the process as shown by the rapid absorption of calomel and the protiodid which are insoluble in water and other vehicles. Off hand, one would expect that soluble preparations, as the bichlorid, would be most rapidly absorbed, and this is probably the case; but this compound is likely to be converted into the insoluble albuminates and sulphids when administered orally, although its rapid absorption from the vagina indicates that it may be absorbed directly and with great rapidity. Fistula experiments have shown that absorption of all compounds occurs principally in the ileum, but is also known to occur in the rectum and doubtless may take place, to some extent, anywhere along the entire gastro-intestinal canal.

Mechanism of Absorption of Mercury Administered by Ingestion.—As previously stated, metallic mercury is not commonly administered as such in pills for the treatment of syphilis, but nevertheless some is swallowed by patients when the inunction and fumigation methods of administration are employed. As will be shortly discussed, it would appear from clinical experiments as well proven that a portion of the mercury applied to the skin in the form of an ointment of the metal (*unguentum hydrargyri* or of calomel) is volatilized by the heat of the body and inhaled, following which a portion is doubtless swallowed in the saliva; the same is true to some extent after fumigation. What is the subsequent fate of this metallic mercury? Are soluble compounds produced, like mercuric chlorid? Numerous authors state that this takes place, but the evidence is not convincing. Even if soluble compounds are formed, may not insoluble albuminates and sulphids be produced in the intestinal contents and mucosa, as is believed to occur after the administration of such soluble salts as mercuric chlorid and the biniodid?

It cannot be said, therefore, that the mechanism of absorption of mercury from the gastro-intestinal canal has been satisfactorily explained. It is likely that by oxidation and other chemical reactions soluble compounds are gradually produced from metallic mercury, albuminates and sulphids, etc., and that these are directly absorbed with the products of digestion into lymphatic and venous channels. But in addition, I believe that a part is directly absorbed in colloidal suspension in the form of minutely divided particles after volatilization and distributed as such by the blood or after oxidation and conversion into true solutions in the blood and other body fluids.

Absorption and Elimination of Mercury Administered by Cutaneous Application.—As stated by Fournier, the administration of mercury by contact with the skin is one of the oldest of all methods of administration. Inunction was employed in the fifteenth century and is mentioned by Fracastor in his poem on syphilis. But, administered in a reckless fashion, "anointed to the point at which the teeth started like the keys of an organ when played on," the method soon led to a violent reaction against it.

Mercury may be administered by this route not only by rubbing ointments of calomel and other insoluble compounds into the skin, but also by the method of fumigation, by wearing mercurial plasters and impregnated flannels or taking tepid bichlorid baths (method of mercurial balneation). Only the inunction method is now commonly employed. Absorption of both soluble and insoluble compounds of mercury may likewise occur from wounds and after applications of solutions and ointments to syphilitic ulcers.

Absorption and Elimination of Mercury Administered by Inunction.—For the inunction treatment of syphilis a drahm of the official blue ointment (*unguentum hydrargyri*) is usually applied; this dose contains 30 grains or 50 per cent. metallic mercury in a finely divided state. Schamberg has employed an ointment containing 45 grains of calomel in a dose, as equivalent to this amount in terms of metallic mercury since calomel contains 85 per cent. of the metal. At the present time both ointments are employed, but the blue ointment to a greater extent than the latter since metallic mercury is more volatile than calomel, is therefore absorbed more readily after cutaneous application and produces better therapeutic results, as will be discussed shortly with more detail.

Before entering upon a discussion of *how* mercury is absorbed when applied to the skin—that is, whether it is absorbed directly or after volatilization and inhalation or by a combination of these two routes—I shall briefly summarize recent experimental studies on the elimination of mercury applied by inunction as an index of the degree of absorption. Wile and Elliott,[4] in a study of the rate of absorption of different salts of mercury, found, after inunctions with 4 gm. of 50 per cent. ointment of mercuric salicylate, 3 gm. of 50 per cent. ointments of the yellow and red oxids and 4 gm. of a 50 per cent. ointment of the oleate, that mercury could be found in the urine in from 48 to 72 hours later, but never in as large amounts as follows inunction with the official ointment of mercury (*unguentum hydrargyri*). Of course a part of the difference in elimination of mercury in these experiments may have been due to variations in the dosage calculated in terms of metallic mercury. But aside from this consideration, additional experiments showed that these compounds have a lower vapor pressure, that is, are less rapidly volatilized at body temperature, than metallic mercury, calomel and ammoniated mercury and that, while inunction is followed by absorption probably directly through the skin, inunction with ointments of compounds more readily vaporized is followed by a greater degree of absorption due to the inhalation and absorption of mercury vapors in addition to that absorbed directly through the skin. In a subsequent study of mercury following inunctions with blue ointment and calomel of presumably equal amounts on the basis of mercury content, Wile and Elliott[5] found mercury in the blood only after a considerable number of inunctions of blue ointment had been given; after a similar number of inunctions with calomel ointment mercury was not found in the blood, indicating that the mercury of blue ointment is absorbed into the blood more rapidly than the mercury of calomel. Inunction with both ointments resulted, however, in the presence of mercury in the milk of nursing women, in saliva and stomach contents, but not in the cerebrospinal fluid. In all instances, however, absorption of mercury from calomel ointment appeared to be slower than from blue ointment, as determined by the rate of elimination.

Lomholt studied the elimination of mercury in the urine and feces in two patients receiving daily inunctions of blue ointment in dose of 3 gm. In both cases a slow but regular increase of the elimination was observed during the first three weeks; afterwards the elimination kept almost stationery at bout 0.003 gm. per day. Even forty days after stopping the inunctions, elimination exceeded 0.0005 gm. per day. The average elimination per day under treatment was 0.00217 and 0.00215 gm. of mercury respectively; the quantity eliminated in the feces amounted to 26.2 and 30.8 per cent. of the total respectively for these two cases, but elimination through the feces was very irregular and without any remarkable increase under treatment.

These and additional studies by Ramsey and Ziegler,[6] Schamberg, Raiziss, Gavron and myself[7] and others have shown, therefore, that application of mercury to the skin is followed by rapid absorption as shown: (1) by the appearance of mercury in the urine and feces; (2) by the production of toxic effects, especially stomatitis and (3) by the production of therapeutic effects which are frequently well marked. The clinical effects alone are so well known that investigation on the subject of elimination was never really required to show that absorption occurred but rather to indicate which preparations of mercury are best absorbed and especially the mechanism of absorption.

Absorption of Mercury Administered by Fumigation.—The treatment of syphilis by mercurial fumigation is nearly as old as the inunction method.

It was in great favor in olden times, and, known as the "treatment by perfumes," constituted an means for securing the "good salivations" which were then considered necessary for eliminating the "corrupt humors" of the disease.

Fumigation as practiced in olden times, with the patient, or rather the victim, inclosed in a chamber and half suffocated with the vapors of mercury and various balsams and other "perfumes," was a combination of mercury treatment by inhalation and cutaneous application; as practiced in more recent years, by placing the patient in a sort of tent with the head outside, it is almost entirely a method of cutaneous application since the mercury condenses on the body in a state of extremely fine division. After this the patient is put to bed for three quarters of an hour, enveloped in the same coverings. The fumigation is repeated every day, every other day, or twice a week, according to the indication of the case.

Undoubtedly mercury may be absorbed by this method of administration, since it has been found in the urine; furthermore, stomatitis may be produced by too frequent administrations. Very probably the mercury deposited on the skin is again volatilized and inhaled, while a small part may be absorbed directly through the glands of the skin either in a state of colloidal division and suspension or after oxidation and conversion into soluble compounds. It is, however, an inconvenient and uncertain method, dangerous and quite unsuitable as a method for the prolonged treatment of syphilis.

The use of *mercurial flannels* is really a form of inhalation therapy. These flannels, well known as "Merget's flannels," are prepared by soaking them in mercuric chlorid solution and afterwards in ammonia, which precipitates the mercury in a state of very fine division. This flannel is then enveloped in lint or gauze and placed on the patient's pillow or suspended around the neck. Bordier has shown experimentally that one of these flannels, eight by ten inches, gives off every hour an average of $\frac{1}{7}$th grain of mercury and nocturnal inhalation for eight hours is said to be sufficient for therapeutic effects. Undoubtedly mercury is inhaled and absorbed by this method as shown by elimination in the urine as well as by toxic and therapeutic effects. But, as stated by Fournier, it is useless as a fundamental method for the mercurial treatment of syphilis.

Mechanism of Absorption of Mercury Administered by Inunction.—In 1888 Merget[8] expressed the opinion that mercury when administered by inunction does not penetrate the skin at all, but is inhaled and absorbed after volatilization on the skin. Since then the subject has been a matter of considerable discussion and only within recent years may it be said that carefully conducted and controlled experiments have shown that mercury can be absorbed directly through the skin, but that in the treatment of syphilis by inunction of blue ointment considerable volatilization of mercury occurs followed by inhalation and swallowing of the vapors.

It has been contended that the intercellular bridges and basement membrane of the unbroken and intact skin forms an impassable barrier to the absorption of a heavy metal, even when so finely divided as is mercury in the form of blue ointment. But following inunctions mercury has been found in the sebaceous and sweat glands, and while it is true that these are excretory, yet it would appear possible for the mercury to find its way into the lymphatics in a state of very fine division or to be picked up and transported to lymphatic and venous channels by the leukocytes. Others maintain that by means of oxidation or chemical conversion by the fatty acids and other substances of the secretions, etc., soluble compounds of mercury are produced with direct absorption through the skin.

While the exact mechanism of absorption through the skin has not been determined, I believe that it may be said, however, that absorption of some mercury does actually occur by this route. Schamberg, Raiziss, Gavron and myself found that rabbits rubbed with calomel and blue ointments and prevented from breathing air in contact with the anointed areas, succumbed to mercurial poisoning with degenerative lesions in the liver and kidneys and with considerable amounts of mercury in these organs, together with a faint trace in the brain, but with no mercury in the lungs. Furthermore, the experiments of Wile and Elliott with ointments of mercuric salicylate, the oxids and oleate have suggested that such mercurial compounds which do not vaporize readily at body temperature and yet show the elimination of mercury in the urine when applied to patients in the form of 50 per cent. ointments, are very probably absorbed in part at least through the skin. Finally Zwick[8a] in a microscopic study of the absorption of mercury from the shaven skin of animals, applied in the form of a fifteen minute rub of mercurial ointment, has shown that mercury is not deposited or absorbed from the intact epidermal layers of cells but is apparently absorbed from the infundibula of the pilosebaceous follicles and the orifices and excretory ducts of the sebaceous glands. In other words the principal depositories were the natural openings of the skin and Zwick concludes that any mercury remaining on the intact epidermis may as well be removed with benzine or carbon tetrachlorid, as advocated by Cole and Sollmann[8b] in their "clean inunction treatment," insofar as absorption is concerned. In this connection it is interesting to note that Cole, Hutton and Sollmann gained the impression, in the course of their investigations, that patients whose skin is abnormally dry tend to be hypersusceptible to mercury, perhaps because such skins are more easily fissured, or perhaps because the ointment can be rubbed more easily into the ducts when the glands are not actively secreting.

But there is no doubt at all concerning the volatilization of mercury and inhalation and swallowing of the invisible vapor when blue ointment is applied to the skin by inunction. I believe that this is the chief means of absorption not only after the application of blue ointment which is the most volatile of mercury preparations, but also after inunction with ointments of less volatile mercury as calomel, etc. Weylander[9] who has studied this subject with particular care believes that the absorption of mercury after inunction with blue ointment occurs only by this route.

Wile and Elliott have also found mercury in the urine of a nurse who had given inunctions to patients with gloved hands over several weeks, and in experiments with calomel and blue ointments smeared on waxed paper, covered with several layers of gauze and applied to the chest in such way that none of the ointment came in contact with the skin, mercury was found in the urine forty-eight hours after the application of blue ointment and ninety-six hours after application of the calomel ointment. In the experiments of Schamberg, Raiziss, Gavron and myself rabbits inhaling air in contact with rabbits rubbed with blue ointment succumbed to mercurial poisoning and mercury was found in the skin, lungs, liver and kidney; these experiments conclusively proved the absorption of volatilized mercury, but animals inhaling air in contact with rabbits rubbed with calomel ointment did not succumb and analyses of the skin, liver, lungs and kidneys did not reveal mercury. In other words, calomel is not as volatile as metallic mercury in blue ointment; consequently it is not absorbed to the same degree. For this reason inunctions of syphilitic patients with calomel ointment does not result in as prompt therapeutic effects as follows inunction with blue ointment, as shown by Cole;[10] neither does calomel ointment produce stomatitis and

salivation as quickly as blue ointment, but yet some mercury is absorbed after inunction with calomel ointment as shown both experimentally and clinically. There can be no doubt that calomel ointment is less objectionable to patients than blue ointment and it is very much hoped that means will be found for rendering it more easily dissociated and volatilized as indicated by the work of Gambier,[11] who claims to have produced a calomel five times lighter and seven and one half times more dissociable than ordinary sublimated calomel.

According to Jenkins,[12] the rate of volatilization of mercury at blood heat is insignificant and, in the inunction treatment of syphilis, mercury is absorbed directly through the skin and not by inhalation and swallowing of vapors; but the experiments of Wile and Elliott have definitely shown that mercury is volatilized at body temperature and there can be no reasonable doubt that some and, indeed, most of the mercury absorbed after application of calomel or blue ointment to the skin, is due to vaporization followed by inhalation and ingestion. Just how the mercury is absorbed in vapor is likewise a matter of divided opinion, which subject will be discussed immediately; I believe that a portion is condensed in the mouth or upper respiratory tract and swallowed with saliva while the balance is absorbed directly through the lungs by much the same mechanism as absorption occurs through the skin.

Absorption and Elimination of Mercury Administered by Inhalation.—There is no doubt regarding the fact that metallic mercury, and to a lesser extent calomel and other salts, volatize at body and even lower temperatures. As discussed above in relation to the absorption of mercury administered in inunction, fumigation or by mercurial flannels and plasters, clinical evidence and experimental results show quite conclusively that a portion of mercury is inhaled when administered by these and similar methods.

Industrial accidents have likewise shown the absorption of mercury by inhalation, as, for example, in the case of the British ship *Triumph*, which in 1810 had some mercury containers broken in her hold and resulting in the poisoning of 200 sailors, three of whom died, as well as the fatal intoxication of all birds and cattle on board. There were also the poisoning of human beings and lower animals by the fumes of mercury from a burning mine in India in 1804 and numerous similar accidents among artisans working with mercury in mirror and thermometer factories, etc.

I have already mentioned the experiments of Schamberg, Raiziss, Gavron and myself with rabbits inhaling air in contact with other rabbits anointed with blue ointment and showing mercurial intoxications with mercury distributed in the lungs, liver, kidneys, etc.; undoubtedly a portion of the mercury was inhaled. Likewise the experiments of Wile and Elliott have been discussed above on the volatilization of metallic and various salts of mercury and the effects produced by inhalation of these vapors. In addition it may be stated that the experiments of von Baerenspring[13] showed that rabbits exposed for one quarter to an hour to the vapor of boiling mercury died within a few days and in one instance, droplets of mercury were found in consolidated areas in the lungs; rabbits kept in a cage with an open dish of mercury became ill in two weeks and died in three weeks. Similar results were observed by Eulenberg, Merget, Skudro, Ricker and Hesse;[14] Solles[15] and Binz[16] cite additional experiments of similar nature and results of earlier investigators.

Recently, however, the experiments of Cole, Gericke and Sollmann[17] have shown in their opinion that in human subjects the inhalation of mercury has no advantage over oral administration but, on the contrary, has the disadvantages of indefinite dosage and special dangers from irritation of the respiratory organs. These investigators administered from 5 to 80 mg. of calomel at a dose, totaling 225 mg. in two weeks, to each of five patients with active syphilitic lesions, by vaporizing the mercury in a strong glass tube about 10 inches long and bent to an angle of about 130 degrees, open at both ends and heated lightly in a Bunsen flame, the patient inhaling the vapor as it was formed by deep inhalations from one end of the tube. A second series of six patients were treated with inhalations of from 5 to 160 mg. of mercury rubbed up in chalk, totaling from 225 mg. in two weeks to 750 mg. in three weeks. In neither series were therapeutic results observed and the calomel proved more irritating than the metallic mercury.

Gutman,[18] however, in a series of experiments with guinea-pigs has amply confirmed the results of earlier investigators and has shown that the inhalation of the vapors of metallic mercury not only produced clinical evidences of intoxication, but also histological changes in the different organs, as well as the deposition of mercury not only in the lungs but in the liver, kidneys and other organs. Gutman has very properly called attention to the fact that vaporization of calomel or other salts of mercury may prove irritating by reason of chlorin or other gases, whereas vaporization of metallic mercury is free of irritating effects unless a concentrated vapor is inhaled.

Without at this time entering into a discussion of the practical aspects of inhalation therapy in the treatment of syphilis, there can be no doubt regarding the fact that mercury is absorbed after inhalation of vapors. In many of the industrial accidents and animal experiments referred to above, it was likely that some mercury was swallowed and probably a portion was absorbed through the skin in some instances at least; but aside from these routes of absorption, the evidence in favor of the absorption of mercury in the air passages may be regarded as conclusively proven.

There is, however, considerable difference of opinion regarding the mechanism of absorption and the practical value of inhalation methods in the treatment of syphilis; the former may, therefore, be discussed at once while the latter will be considered in a later chapter.

Mechanism of Absorption of Mercury after Inhalation.—In the first place does mercury inhaled as a vapor reach the alveoli or deeper tissues of the lungs, or is it condensed and deposited in the nose, mouth, pharynx and upper respiratory tract? I believe that the early experiments of Merget and von Baerenspring who found mercury in the lungs of rabbits exposed to the vapors of mercury, as well as those of Schamberg, Raiziss, Gavron and myself who found mercury in the lungs of rabbits inhaling vapors from the skin of rabbits anointed with blue ointment, and the experiments of Gutman who not only found mercury in the lungs of guinea-pigs by chemical analyses but demonstrated mercury in these tissues by having the animals inhale iodin immediately after the inhalation of mercury with the deposition of mercuric iodid—show quite conclusively that some mercury at least reaches these deeper tissues. Insofar as chemical analyses of the lungs are concerned, it is of course possible and indeed probable that some of the recovered mercury was from the blood; but aside from this possibility, I do not personally doubt that some of the vapor may actually reach the alveoli. Indeed, the rapidity with which mercury is ordinarily absorbed after the inhalation of mercury vapors, as judged both by clinical effects and analyses of the blood, indicates in itself in my opinion that the absorbing area must be greater than that represented by the upper respiratory passages together with the small amounts that may be absorbed after ingestion.

Granting that mercurial vapors may reach the deeper tissues of the lungs, how does absorption occur? Is it possible for the mercury to pass directly through the two layers of endothelium into the capillaries or is it first condensed and later absorbed? These questions have never been satisfactorily answered. According to Hermann,[19] Furbringer[20] and others, the mercury is first deposited since only soluble gases are believed capable of passing into the blood. Cole, Gericke and Sollmann state as their belief that most of the mercury is deposited in the upper air passages and that if any reaches the alveoli it is first deposited there before absorption; Gutman states that the vapor may be absorbed direct without primary deposition. Certainly there is no valid reason for believing that all of the inhaled mercury is deposited because at body temperature mercury is known to be volatile in the presence of moisture. As stated above, this point has never been definitely settled, although Merget's experiments with the lungs of frogs indicates that the

vapor may be absorbed direct into the blood since passage was so rapid as to be described as "instantaneous."

Neither do we know how mercury deposited in the nose, trachea bronchi and alveoli is absorbed; in the lungs doubtless a portion may be picked up by phagocytes just as particles of coal and other inorganic dusts are known to be carried into the interstitial tissues and glands Whatever the mechanism may be, it is similar to absorption through the skin. Personally, I believe a portion may be absorbed directly into the blood in a state of extremely fine division; possibly a portion, the major portion, is oxidized and by other chemical changes converted into soluble compounds which are readily absorbed. The absorption of mercury through the air passages is, therefore, a rapid process and doubtless accounts in large part for the successful administration of mercury by inunctions with blue ointment. The mercury inhaled in the form of a vapor may be in part absorbed direct without condensation; a part of that which is condensed may still be absorbed direct or after being rendered soluble by oxidation and other chemical processes which are not as yet understood.

Absorption and Elimination of Mercury Administered by Injection.—A distinct advantage of administering mercury by injection is accuracy in dosage. This is true insofar as it relates to the deposition of a certain dose in the subcutaneous or intramuscular tissues or directly into a vein or the subarachnoid space of the meninges, but when injected into the tissues it does not necessarily follow that absorption will occur in a regular and uniform manner and with all methods of injection the degree of dissociation of the active mercury ions depends upon the composition of the compound injected. In other words, the injection of a full or half complex organic compound with very firm union of mercury with the carbon nucleus may be followed by elimination of a large proportion of the dose in an unchanged form and consequently the compound may be relatively non-toxic and without much therapeutic activity. Similarly the intramuscular injection of metallic mercury in the form of gray oil (*oleum cinereum*) is followed by irregular and slow absorption, so that while the injection of mercury may readily enough satisfy the physician and patient that a certain dose has been given, it does not necessarily follow that absorption and therapeutic activity are under similar control unless care is taken in the choice of compound injected to avoid irregular and cumulative effects.

Absorption and Elimination of Mercury after Intravenous Injection.—A large number of soluble mercurial compounds—inorganic and organic—have been advocated for intravenous injection in the treatment of syphilis. In some instances insoluble compounds in colloidal suspension have likewise been injected. Of course the question of absorption does not enter here, insofar as absorption into the blood is concerned. Just what proportion of the injected dose reaches the foci of syphilitic infection and becomes therapeutically active is, however, a different matter and varies with the chemical composition of the drug. For example, organic compounds of the half or full complex variety are likely to be largely eliminated before dissociation of the mercury ion can occur.

Elimination after intravenous injection is ordinarily a rapid process, mercury being sometimes found in the urine within an hour after the injection of such inorganic salts as mercuric chlorid or the red mercuric iodid in doses varying from $\frac{1}{3}$ to $\frac{1}{6}$ grain. Elimination is usually complete within forty-eight to seventy-two hours, 75 per cent. or more of the injected mercury being recovered in the urine and feces in these periods of time; for this reason it has been found necessary to repeat intravenous injections of mercury at intervals

of one to three days when this route of administration is employed in the treatment of syphilis.

Absorption of Mercury after Subcutaneous and Intramuscular Injections of Water-soluble Compounds.—A very large number of soluble compounds of mercury have been likewise advocated for subcutaneous or intramuscular injection, since mercuric chlorid, among the first employed, was found to be quite irritating. Among the insoluble compounds, metallic mercury in the form of gray oil, calomel and mercuric salicylate have been mostly employed.

The water-soluble salts are of course more rapidly absorbed than the insoluble; in the case of both classes of compounds, however, the degree of absorption is influenced by the degree of inflammatory changes induced by the drug in the tissues, just as the rapidity of absorption of the organic arsenical compounds is influenced by this factor. Furthermore, with the insoluble compounds the degree of absorption is influenced by the kind of compound injected, being very slow in the case of gray oil and most rapid with the salicylate. The rapidity of absorption is likewise influenced to some extent by the menstrum employed, being more rapid when the compound is suspended in vegetable and animal oils than in mineral oils.

With both soluble and insoluble compounds the rate of absorption is likewise influenced to some extent according to the site of injection, being more rapid from the muscles than from the subcutaneous tissues or between the sheaths of muscles. Furthermore, mercury deposited in muscles subject to active exercise and pressure is probably more quickly absorbed than from muscles less physically active.

Lomholt has studied the rate of absorption and elimination of benzoate of mercury by injecting two patients intramuscularly with 0.1 gm. once a week; since the compound contained 43.5 per cent. mercury, this dose represented the injection of about 0.04 gm. of pure mercury. On the day following an injection, from 0.005 to 0.01232 gm. of mercury was eliminated. During the balance of the week the elimination gradually decreased to about 0.001 to 0.002 gm. on the sixth or seventh days. Elimination in the feces was more irregular and only about 21.4 per cent. of the total eliminated was found in the feces. During the period of thirty-four to forty days of treatment (five to six injections), about 35 to 48 per cent. of the total mercury injected was recovered in the urine and feces showing that about 50 to 60 per cent. was retained for longer periods of time.

Lomholt also injected a rabbit intramuscularly six times at short intervals during a period of twelve days with a dose of 0.75 c.c. of a 2 per cent. solution of the benzoate (corresponding to 0.0063 gm. of pure mercury per dose or a total of 0.0378 gm. in six doses). During this period 0.00621 gm. of pure mercury was eliminated in the urine and feces; 0.0207 gm. was found in the muscles; 0.00794 gm. in the balance of the tissues and 0.00295 gm. lost in the experiment. This experiment showed, therefore, that about 16 per cent. of the injected mercury was eliminated during the time of treatment, while about 53 per cent. of the injected mercury was eliminated during the time of treatment, while about 53 per cent. was retained in the muscles at the site of injection and 23 per cent. in the other tissues and organs.

Ordinarily we believe that absorption is more complete from the muscles than indicated by these results, but doubtless the production of albuminates of mercury in the muscles, along with inflammatory reactions, reduce the rate of absorption and due care must be exercised against cumulative effects as is true when the water insoluble compounds of mercury are injected. Data is not available on the comparative rates of absorption of the large number of water soluble compounds of mercury that have been advocated from time to time for subcutaneous or intramuscular injection in the treatment of syphilis. Probably the rate for all is similar to that found by Lomholt for the benzoate since the majority precipitate proteins and form albuminates which are slowly soluble; the degree of local irritation, however, varies with different compounds, and in the case of mercurophen, at least, I know varies

to some extent with different lots of the same compound. Doubtless the degree of local reaction influences absorption, but not to the extent of requiring serious consideration in relation to the treatment of syphilis.

Judged mainly on the basis of toxicity tests among the lower animals absorption of mercury from the muscles is somewhat more rapid than from the subcutaneous tissues; clinical observations also confirm this statement in relation not only to the soluble and insoluble compounds of mercury but to drugs in general. Absorption from fatty tissues is particularly slow and necrosis is more likely to follow than when mercury is deposited in fibrous tissue or muscles.

Absorption of Mercury after the Intramuscular Injection of Water-insoluble Compounds.—In this connection most interest is placed in the intramuscular injection of gray oil, calomel and mercuric salicylate in vegetable or animal oils.

In 1915, Schamberg, Raiziss and myself[21] studied the rate of absorption of these compounds from the muscles of rabbits and found that 40 to 50 days later as much as 46 to 48 per cent. remained inabsorbed while 71 per cent. was recovered 21 days after injection.

Lomholt found that the salicylate of mercury was absorbed and eliminated more rapidly than calomel and metallic mercury in gray oil in both human subjects and rabbits. He states that this is due to the fact that the salicylate is very difficult of dissociation and that it may be absorbed and eliminated unchanged; needless to state this is a factor of great importance in relation to toxicity and the treatment of syphilis, as I shall discuss with more detail in later chapters. Lomholt also administered these compounds to syphilitic patients and analyzed the urine and feces for mercury to arrive at the approximate amounts eliminated and retained and found a retention of 50 to 90 per cent. after 4 to 6 doses at intervals of 5 days.

The elimination of mercury after the salicylate injections was irregular and after the period of ten days from 50–60 per cent. of the injected mercury was apparently retained; elimination after the calomel injections was more regular, but at the end of ten days about 75 per cent. had been retained. The curve of elimination after the gray oil injections was very surprising; during the first fourteen days only small amounts were eliminated (less than 0.001 gm. per day), when a sudden increase occurred with the elimination of 0.005 gm. per day for more than six days. It will be noted, however, that during the entire period of eighteen days, only 9.6 per cent. of the injected mercury was eliminated in the urine and feces leaving about 90 per cent. in the tissues and largely in the muscles where the injections had been given. Of interest in this connection is the statement that some months later the patient suddenly developed severe mercurial intoxication while engaged in hard labor and without receiving any additional treatment. This indicated that the mercury had probably been encapsulated in the muscles, with sudden absorption probably the result of scattering of the "depots" as a result of muscular movements.

Even more instructive information has been secured by Lomholt in experiments with rabbits injected intramuscularly with these three drugs; it was observed that approximately only 30, 10 and 5 per cent. of the mercury injected as the salicylate, calomel and gray oil, respectively, was eliminated during the ten to eighteen days of observation, while about 35, 55 and 75 per cent., respectively, was retained in the muscles at the sites of injection. These experiments showed that the mercury of the salicylate is eliminated most rapidly and the metallic mercury of the gray oil least, while that of calomel is intermediate. In the experiments of Schamberg, Raiziss and myself described above, the salicylate was likewise found to be much more rapidly absorbed than either calomel or gray oil, although the difference in the rate of absorption of the last two drugs was not as great as observed by Lomholt.

Fournier[22] states that Oudin and Barthélemy made roentgenograms of gray oil injections and observed that after the fourth day scarcely any traces of the metal remained in the muscles. In a recent and admirable study of the same kind by Cole, Littmann and Sollmann,[23] these results were not confirmed. The authors concluded that gray oil injections are absorbed so slowly and with such danger of cumulative effects, that they should be abandoned in the treatment of syphilis as inefficient and dangerous; the salicylate was regarded as best adapted for intramuscular injections. In this connection it should be stated that soluble salts of mercury did not throw shadows on photographic plates and that their absorption could not be studied by this method.

Mechanism of Absorption of Water-soluble and Insoluble Compounds of Mercury after Injection.—The majority of the soluble salts of mercury pre-

cipitate proteins and doubtless some degree of precipitation occurs when these are injected subcutaneously or intramuscularly. This precipitation bears no relation to the amount of metallic mercury but on the nature of the compound—that is, whether organic or inorganic—and the strength of the acid from which a particular salt is derived. These factors operate by influencing the degree of dissociation or ionization of the mercury and no chemical reaction can occur while the mercury is in a non-ionized state. For example, mercuric chlorid and mercury sulphate being salts of inorganic acids ionize and precipitate proteins more actively than such salts of the weaker organic acids as the acetate, oxycyanid, cyanid, and cacodylate of mercury, although both of the inorganic salts mentioned contain less mercury than one of these salts of an organic acid, namely, the oxycyanid. Furthermore, mercuric chlorid containing 74 per cent. mercury precipitates less than the sulphate containing 67 per cent. and of the salts of the organic acids, the oxycyanid containing 83 per cent. mercury is hardly more active in precipitating proteins than the cacodylate with but 20 per cent. mercury.

Mercurophen and the succinimid of mercury do not precipitate proteins at all, except in very concentrated solutions (1:100) and it is highly probable that these and other salts of the organic acids are somewhat more quickly absorbed than mercuric chlorid and other salts of the inorganic acids. However, all of these soluble compounds probably produce some precipitation of the proteins of the tissue juices and plasma upon subcutaneous and intramuscular injection with the production of water insoluble albuminates.

It is not definitely known, however, how these albuminates or other water-insoluble compounds of mercury, as the metal itself (gray oil), calomel and salicylate, are absorbed. All produce some tissue necrosis and exert a positive chemotaxis upon polymorphonuclear leukocytes and other wandering cells; it is commonly believed that these cells pick up particles of the mercurial compounds and transport them to the blood and lymph and largely in their nuclei. In addition, it is highly probable that chemical processes result in the gradual production of soluble compounds which are absorbed into the lymph and blood. Oxidation doubtless plays some part in the production of these soluble compounds and especially in conversion and absorption of metallic mercury; since the mercury in gray oil is deposited in a mass, its conversion into soluble compounds and absorption is much slower than occurs in the respiratory tract and skin following the administration of metallic mercury by inunction or inhalation of vapors.

Physical State of Mercurial Compounds in Relation to Absorption and Elimination.—It is quite evident, therefore, that both the physical state and chemical composition of the various soluble and insoluble compounds of mercury employed in the treatment of syphilis bear an important relation to the rapidity of absorption and elimination and, as will be discussed in succeeding chapters, an even more important relation to toxicity and therapeutic activity.

By physical state I refer both to the divisibility or volatility of the mercurial compound at body temperature and the degree of divisibility at the time of administration. For example, while all mercurial compounds may be said to possess some degree of volatility at body temperature, metallic mercury is most volatile and consequently best adapted for administration by inunction or inhalation. But the degree of divisibility at the time of administration also exerts an influence; for example, finely divided metallic mercury in ointment is more volatile than the same amount in mass and it is partly for this reason that the ingestion of metallic mercury is followed by very much less absorption than when the same amount is finely divided and smeared on

the skin or incorporated in flannel or with chalk and hung around the neck. It is obvious, however, that the degree of division and facility for volatilization do not play any important part in the rate of absorption when mercurial compounds are administered by injection; under these circumstances, chemical processes are far more important, and especially oxidation with the conversion of mercurous to mercuric compounds and other chemical reactions concerned in the production of soluble compounds.

While the rate of decomposition or ionization of the compounds into the mercurial ions apparently influences the production of albuminates and these in turn the rate of absorption, yet ionization is not nearly so important in relation to the absorption of the compound as it is to toxicity and therapeutic activity. The salicylate of mercury, for example, is a pseudo- or half-complex compound, in which only one of the two valencies of the divalent mercury is connected to the carboxyl of the acid, the other being connected directly to the carbon of the benzene nucleus; as a result, the salicylate is less easily decomposed than some other compounds and its lower toxicity appears to be due to this slow dissociation or ionization. For this reason some of the salicylate may be excreted unchanged. This factor may also influence the rate of production of albuminates in the tissues and these in turn may influence the rate of absorption, although the importance of this factor is not to be emphasized, since the albuminates are readily absorbed, as shown by the rapid absorption of those formed by the soluble salts of the inorganic acids as when mercuric chlorid is injected subcutaneously or intramuscularly.

Distribution of Mercury after Absorption.—It is highly probable that mercury is distributed in the blood in the form in which it is absorbed and, as stated above, this is influenced to some extent by the ionization capacity of the compound. Metallic mercury is first oxidized and mercurous salts are converted into mercuric compounds; with the ionizable compounds albuminates are now produced and most investigators have affirmed that the mercury circulates as such. After intravenous injection it is believed that the same changes occur. In the case of compounds which do not ionize at all as the full complex organic compounds, or, those that ionize partially as the half-complex and pseudocomplex compounds, as mercuric salicylate, it is believed that a portion may be absorbed unchanged and be excreted as such. It is difficult to understand, however, the form in which such a compound circulates, unless in colloidal suspension or within the leukocytes.

Lomholt states in this connection that his analyses have shown mercury in the leukocytes and while the amounts were relatively small, owing to the small numbers of leukocytes in the blood, yet the amount per leukocyte was large. It is likewise possible that metallic mercury may be absorbed through the skin and alveoli of the lungs in a state of extremely fine division and be transported in colloidal form or after being picked up by the leukocytes and thereby carried in the blood. Lomholt has also found mercury in the erythrocytes and plasma, mostly in the latter; fractional precipitation of the serum with ammonium sulphate showed equal amounts in the albumin and globulin fractions. According to this investigator the saturation point of the blood is about 0.003 gm. per 1000 c.c.; when this amount is exceeded elimination occurs. Rosenbloom[24] found as much as 0.012 gm. per liter of blood in a case of acute poisoning.

After reaching the lymph and blood, mercury is widely distributed throughout the body and is found in almost every organ including the spleen, lungs, intestine, buccal mucosa, brain, muscles and bones. Lomholt states that it is transmitted through the placenta to the fetus and this is well substantiated by clinical experience. He also found traces in ascites fluid,

which is to be expected when collections occur at a time when mercury is present in the blood. Larger amounts are found in the kidney, intestinal wall and liver than elsewhere; considerable amounts are usually deposited in the liver. This distribution occurs in both acute poisoning and during prolonged administration regardless of the route of administration. According to Lomholt, the kidneys contain the highest concentration, namely, 0.0016 gm. per 100 grams in a treated case, and 0.017 gm. per 100 grams in a poisoned case. The liver was next in percentage content and first in actual content among the internal organs, owing to its large size. The intestinal walls contain the next largest amount in point of percentage. It is highly probable that high concentrations also occur in syphilitic lesions and especially those involving bone; of interest in this connection was the finding by Mastin and myself[25] of an enormous number of globules of metallic mercury in the tissues of aneurysm of the descending aorta involving the dorsal vertebrae. As early as 1579, Fernel[26] states in his work on the venereal disease that metallic mercury may be found in the "putrid caries of bones" if the patient has been exposed to the vapor of mercury or of cinnabar, and also in those who have had repeated rubbings with the ointment. Since then, several observers have recorded the presence of metallic mercury in the necrotic bones of syphilitics receiving vigorous mercurial treatment; the literature of the last twenty-five years, however, contains but few records, owing probably to the practice of less vigorous dosage with mercury in the treatment of syphilis. In our case we could not ascertain from the patient the form in which mercury had been taken. A second aneurysm of the first portion of the descending aorta, but not involving bone, did not show the presence of these globules of mercury.

Mercury in the Brain and Cerebrospinal Fluid.—As stated above traces of mercury have usually been found in the brain. This occured in the rabbit experiments of Schamberg, Raiziss, Gavron and myself following inunctions with blue ointment and various observers have found traces by chemical analyses in the brains of the lower animals treated in various ways with mercurial compounds, as well as in the brains of human subjects succumbing to mercurial intoxication. These findings are of considerable interest in relation to the treatment of neurosyphilis, as are the results of studies on the presence of mercury in the cerebrospinal fluid. Wile and Elliott[27] found none in the spinal fluid of patients after inunctions with blue and calomel ointments, and following injections of the salicylate, succinimid and bichlorid. In no case were they able to detect the faintest trace by Elliott's method. Believing that perhaps the amount of fluid tested was too small, they examined the fluids from several different cases that had been taking mercury in various forms for a long period of time. The results were likewise negative. They were able, furthermore, to test the fluid of a patient who died of mercurial poisoning from the ingestion of bichlorid; these results were also negative. Lomholt, however, claims to have found approximately 0.0004 gm. per liter in the spinal fluids of treated cases. Others have also claimed that traces are to be found after prolonged administration or in acute bichlorid poisoning, but the matter of penetration of mercury to the cerebrospinal fluid is still undecided. It is sometimes stated that spinal drainage after the method of Dercum and Gilpin, which consists in the removal of spinal fluid until the flow is reduced to only a few drops per minute, at a time when the patient is under vigorous mercurial treatment, results in an increase of mercury reaching the tissues of the cord and brain and the spinal fluid. These effects are suggested by similar results in the penetration of arsenic, which is also a heavy metal, during treatment with arsphenamin or its substitutes; likewise

by signs of improvement in the spinal fluid and the patient. But actual proof that the penetration of mercury is increased by this procedure cannot be said to have been furnished by chemical analyses of the spinal fluid. It is also possible that intraspinal injections of mercurialized serum or other substances may increase the penetration of mercury to these tissues and the spinal fluid, if mercury happens to be in the blood, by producing localized areas of passive hyperemia with extravasation of plasma (the so-called "aseptic meningitis"), but definite proof in the form of chemical analyses for mercury under these conditions has not been furnished.

The subject has not, however, attracted the attention it deserves in relation to the treatment of neurosyphilis. Mercury dissolved in serum has been injected directly into the spinal subarachanoid space in the treatment of neurosyphilis, but this subject will be discussed in a later chapter.

Retention and Elimination of Mercury in Relation to the Treatment of Syphilis. *Storage or "Depots" of Mercury.*—The elimination of mercury in the urine and feces has already been briefly alluded to in this chapter in relation to the administration of mercury in different forms and by varying routes. In the treatment of syphilis absorption usually proceeds more rapidly than elimination, which results in storage, at least for a time. If the administration is moderate, a state of equilibrium is gradually reached during which excretion may keep pace with absorption. If absorption exceeds excretion beyond a certain point, symptoms of toxicity may appear, which, however, in mild cases tends to gradually disappear if absorption ceases or is reduced while elimination is maintained. The problem in the treatment of syphilis is, therefore, to choose the compound, dose and route of administration which will result in the maximum degree of storage without injury, on the basis that the best therapeutic results will follow when absorption and elimination are so adjusted that the maximum non-toxic amounts of mercury are available in the blood and infected tissues over a long period of time. Lomholt has calculated that the blood may carry from 0.001 to 0.003 gm. of mercury per liter without producing toxic tissue changes and symptoms and that the tissues of an adult may store from 0.090 to 0.150 gm. without toxic effects after about forty inunctions.

As previously stated, however, mercury tends to accumulate in the tissues under all forms of administration; this tendency is least marked with intravenous injections of the soluble salts and most marked following intramuscular injections of gray oil. Among the other insoluble salts commonly employed in the treatment of syphilis, the salicylate is less likely to accumulate than calomel, because a portion of the salicylate may be absorbed and eliminated unchanged without as much tendency to form combinations with the tissue proteins and thereby become stored.

Therapeutic Activity of Stored Mercury.—An important question now arises: is the stored mercury therapeutically active? As discussed in a preceding chapter, it does not appear that stored arsenic from arsphenamin or its substitutes is active because of continued oxidation to relatively inert pentavalent compounds. But I am convinced that stored mercury is therapeutically active and that due consideration should be given this factor in our treatment of *chronic* syphilis. My opinion, however, is based entirely upon clinical results and not upon actual animal tests with emulsions of mercury laden tissues. I have commonly observed that, after a course of mercury, the complement-fixation test may still yield a positive reaction and lesions may still be present in the skin, periosteum, etc., but that after a rest of weeks or months without treatment the serum reaction becomes gradually weaker and the lesions continue to heal. I believe that it is a com-

mon mistake in the treatment of *chronic* syphilis to "push" treatment too hard and largely because the Wassermann reaction remains positive; I have learned that to give courses of treatment of four to six weeks' duration, followed by periods of three to four months of rest, yields best results in the treatment of *chronic* active and *especially of chronic latent syphilis;* one is frequently surprised with the results to be secured by what may be called mild, but persistent efforts of this kind even in the so-called Wassermann-fast cases; but I shall discuss this matter with more detail in chapters devoted to the treatment of chronic syphilis. Here it may be stated, however, that the problem is entirely different in acute early syphilis; it is my opinion that mercury has much less value in this stage since it does not work "fast enough" and that preference should always be given arsphenamin or its substitutes unless a contraindication exists to their administration.

Equilibrium between the Absorption and Elimination of Mercury.—As stated above, the ideal administration of mercury may be said to call for rapidly storing in the tissues the maximum amount free of producing tissue injury and toxic effects, and, according to Lomholt, maintaining from 0.001 to 0.003 gm. per liter in the blood over periods of say four to six weeks at a time.

For this purpose *intravenous injections* of soluble salts may be acquired every day or every other day, since the dose must be small and elimination is rapid with slow storage or accumulation.

Intramuscular injections of the ordinary soluble salts would appear to be required about twice weekly in doses of ¼ to ⅙ grain according to Lomholt's observations with the benzoate and about 50 per cent. of the mercury is retained and stored. Intramuscular injections of the salicylate are apparently required at least in the first part of a course, about every five days in dose of 1 grain, since it is the most rapidly eliminated of the insoluble salts; 55 per cent. tends to accumulate, which is less than with calomel or gray oil. As accumulation occurs, the intervals between doses should be gradually lengthened. Calomel in dose of about 1 grain should be given every 5–7 days, since it is more slowly absorbed and eliminated, about 75 per cent. being retained and stored. For this reason the intervals should be likewise gradually lengthened instead of being kept uniform. Gray oil in dose of about 1 grain of mercury may be given at first every 5 to 7 days but, because it shows the greatest tendency for accumulation (90 per cent.) with only about 10 per cent. elimination, the intervals between injections must be gradually lengthened to avoid sudden or progressive toxic effects even after a course of injections has terminated.

Absorption and elimination after inunctions of blue and calomel ointments is more difficult to gauge as likewise, after ingestion of the protiodid or bichlorid of mercury since absorption is apt to be more irregular. It is well known, however, that storage occurs; probably about 50 per cent. of mercury is stored after inunctions with blue ointment so that, while daily rubbings with 1 to 3 drahms may be permissible for the first week or two, the dose and frequency should be then reduced in order to avoid over storage and toxic effects.

It is readily understood, therefore, that the administration of mercury in the treatment of syphilis should take into consideration these very important factors of absorption, storage and elimination and I shall discuss the subject in this relation with more detail in chapters devoted to treatment. As far as possible an effort should be made to maintain a balance between absorption and elimination, and the studies of Lomholt have aided us greatly in the practical administration of various well known mercurial compounds in the treatment of chronic syphilis.

In practice, however, this ideal of equilibrium between absorption and elimination is very difficult to attain, because the degree of absorption is never known unless the mercury compound is injected intravenously and elimination through the urine and feces requires intricate and laborious chemical analyses; furthermore, as stated above, it is likely that some mercurial compounds are eliminated unchanged in which the medicament may have exerted no therapeutic effects. At best we can obtain only approximate results by careful consideration of the known facts concerning absorption, elimination and retention of mercury in relation to different compounds employed in the treatment of syphilis and in relation to the different possible routes of their administration, as well as by careful observation for the clinical evidences of tissue injury, poisoning and therapeutic results.

Just how long elimination continues after cessation of treatment is difficult to state and varies, of course, according to the kind of compound employed, the dose and route of administration, the duration of treatment and the condition of the two main enunctories, namely, the kidneys and liver. After the intravenous injection of the soluble compounds elimination is most rapid and slowest after the injection of metallic mercury in gray oil.

Elimination of Mercury in the Urine, Bile and Feces.—The largest amounts of mercury are eliminated in the urine. Lomholt has estimated that from ⅔ to ⅚ of the total eliminated escapes by this route. Elimination in the urine is usually regular and uniform although, as previously stated, it varies according to the kind of compound and route of administration. After the intravenous injection of soluble salts, mercury may be found in the urine within an hour and is rapidly eliminated. After the intramuscular injection of soluble salts, mercury is generally found in the urine in twelve to twenty-four hours, as likewise after the inhalation of vapors. After inunction with blue ointment mercury may be found in the urine in twenty-four hours, absorption and elimination being usually later, however, after inunctions with calomel.

Elimination of mercury through the kidneys usually produces a diuresis, which is sometimes made use of in the treatment of cardiac dropsy. According to Lomholt, there does not appear to be a uniform relation, however, between the quantity of urine excreted and the mercury content, but the elimination of very large amounts of mercury always seems to be accompanied by the passage of large amounts of urine. Roughly from 65 to 80 per cent. of all mercury eliminated is excreted by the kidneys in the urine.

While excretion in the urine parallels absorption to a certain degree and while there is no limit to the amount of mercury that may be absorbed, there is a distinct maximum limit to excretion by the kidneys without damage to these organs which Lomholt has estimated at about 0.009 gm. per day; when this amount is exceeded, tissue injury may result.

Nothing is known of the chemical form in which mercury occurs in the urine; with the half and full complex organic compounds it is possible that portions may be eliminated unchanged.

Elimination by the bile and intestines rank next in importance. Lomholt has found from 0.0075 to 0.0165 gm. per liter of bile of animals. Approximately 20 to 35 per cent. of the total elimination of mercury occurs in the feces. It is entirely likely that a portion eliminated in the bile is resorbed lower down in the intestinal tract with a repetition of the cycle of absorption and elimination and accounting in part for prolonged elimination after cessation of administration.

Mercury has been found in the pancreas of animals treated with various compounds and likewise in the pancreas of fatal cases of bichlorid poisoning of human beings; it is probable, therefore, that mercury may be stored in this organ during the treatment of syphilis and that a portion may be excreted with the pancreatic secretions, but this has not been proven by direct experimental investigation.

Elimination through the intestinal walls, and particularly by the colon, has long engaged a great deal of attention since pathological changes are so prominent in the mucosa in cases of poisoning. Chemical analyses have shown mercury in the intestinal walls and it is generally believed that excretion occurs through the glands of the mucosa. Since mercury is also excreted by the buccal mucosa, or, at least, may be present in the gums just as may occur in lead and bismuth poisoning, it is highly probable that some mercury is eliminated by these channels. However, it is also possible and indeed probable, that some of the mercury found by analysis in the intestinal walls is due to absorption into the lymph channels of mercury eliminated in the bile or after ingestion and that the necrotic changes in the mucosa of the colon may be produced by the local irritation of mercury in the intestinal

contents. The investigations of Lomholt have shown that while elimination of mercury in the urine usually fluctuates with regularity according to the amount of mercury administered, elimination in the feces shows no regularity, but is quite irregular, varying from day to day in an unaccountable manner. Lomholt also noted that the quantity and consistency of the feces bore no relation to the mercury content although the larger amounts were found in feces of soft or fluid consistency.

Wile and Elliott have found traces of mercury in the stomach washings after several inunctions with blue and calomel ointments. Whether the mercury was eliminated by the mucosa or swallowed in the saliva, could not be determined; personally I believe that the latter was probably the case since available data indicates that while both mercury and bismuth are eliminated in the mouth, lower ileum and first portion of the colon, that elimination does not occur in the stomach.

Nothing is definitely known of the chemical form in which mercury is eliminated in the bile and gastro-intestinal mucosa. After reaching the intestinal contents albuminates are formed and in the colon, sulphids may be produced in addition. Of course when metallic mercury and its salts are administered by ingestion, portions may be passed unchanged. Likewise it is possible that half and full complex organic compounds administered by injection may be eliminated in part unchanged, owing to failure of dissociation in the blood and tissues. Otherwise it is commonly believed that mercury in the feces occurs as the insoluble albuminates and sulphids.

Elimination of Mercury in the Milk, Saliva and Perspiration.—In 1900 Legales and Duperoy[28] stated that mercury could be found in the milk of women who were being treated with mercurial compounds, and in amounts sufficient to be of value in the treatment of syphilitic infants. Clinical evidence abundantly supports these findings since it is well known that mercurial treatment of syphilitic mothers favorably influences the disease in their syphilitic children. Recently Wile and Elliott have also found mercury in the milk of several nursing women when tested one week after treatment with inunctions; to avoid the possibility of the milk being contaminated by the skin, injections of bichlorid were given and mercury was found in the milk forty-eight hours later.

Traces of mercury have likewise been found in the saliva and perspiration. Elimination by the salivary glands has, of course, been long accepted largely on the grounds that salivation is such a prominent sign of mercurial intoxication. But actual analyses of the saliva have usually shown that only traces may be present and, in some instances at least, the recovered mercury may have been due to condensation and deposition of mercury vaporized from the body during inunction treatment rather than as a result of excretion by the glands. For example, I believe that this possibility existed in the analyses reported by Wile and Elliott, who found mercury in the saliva of patients after inunctions with blue and calomel ointments and the dressing of a syphilitic ulcer with wet applications of bichlorid, without any evidences of stomatitis or salivation.

Mechanism of Therapeutic Activity of Mercury in Syphilis.—That mercury is therapeutically useful in syphilis is abundantly substantiated by centuries of clinical experience. Doubtless cures have been effected in many cases although the number of these as gauged by the modern criteria of more extensive clinical knowledge of the lesions of chronic and latent syphilis combined with the Wassermann reaction of the blood serum and spinal fluid, roentgenologic examinations, etc., is not as large as was believed ten to fifteen years ago. Undoubtedly mercury may dissipate the obvious lesions of syphilis and, when taken over long periods of time according to Fournier's methods, the famous "chronic intermittent treatment," may maintain a state of freedom from obvious lesions and symptoms for many years. But actual and complete cure in the sense of complete eradication of all spirochetes from the tissues is of doubtful occurrence; certainly this result cannot be brought about by treatment with mercury alone in the majority of cases and especially when treatment is begun after the first year of infection.

Just how mercury brings about curative effects in syphilis is not definitely known; the subject is discussed with more detail in Chapter XXIV. Lomholt is of the opinion that not enough mercury can be maintained in the tissues and blood without toxic reactions and over sufficiently long periods of time, to bring about direct spirocheticidal effects in human syphilis, since the experiments of Kissmeyer have indicated that spirochetes may be cul-

tivated in horse serum containing as much as 0.020 gm. of mercuric chlorid per liter.

In his opinion mercury acts by stimulating the tissues to produce spirocheticidal antibodies, but direct evidence of this is lacking, as I have already discussed in Chapter XXIV.

It is my opinion that the curative effects of mercury in syphilis are due to the direct spirocheticidal effects of the mercury ions. Toxicity for the cells of the host is likewise due to the same ions, but it is possible to secure spirocheticidal effects without toxic effects through the accumulation of mercury in the syphilized or infected tissues. Both toxicity and spirocheticidal activities vary among different compounds of mercury according to the rapidity and ease with which the ions are dissociated before elimination occurs; with the salicylate of mercury and flumerin, for example, elimination of unchanged drug may occur before dissociation takes place which accounts for their lower toxicity and likewise lower spirocheticidal activity so that the chemotherapeutic indices of single doses are about the same as mercuric chlorid.

Insofar as the destruction of spirochetes in the blood is concerned, it would appear that almost the maximum tolerated doses of all mercury compounds are required for this result. Therefore, in general terms, mercury is not suitable for the treatment of syphilis in its acute, early, spirochetemic stages. And why is this the case? Because when mercury is injected intravenously it is eliminated so rapidly that the injections must be made at almost daily intervals to maintain sufficient mercury in the blood for spirocheticidal effects and while these amounts may not be toxic for such organs as the heart, pancreas, central nervous system, etc., they may be for those organs concerned in elimination as the kidneys and liver, because so much mercury is brought to them for excretion. In other words the affinity of mercury ions for *Spirochæta pallida* is undoubtedly greater than for the body cells in general, but to maintain spirocheticidal amounts in the blood over a sufficient period for curative effects may result in the accumulation of toxic amounts in the eliminating organs and especially the kidneys. Rapid elimination after intravenous injections accounts for the fact that the acute early lesions of the skin and mucous membranes may not be greatly influenced at all or only as long as the injections are given at daily or every two day intervals. For this reason I believe that arsphenamin, neoarsphenamin or their substitutes are always to be preferred in the treatment of syphilis in its acute early stages, because the toxicity of these for all body cells, including the excretory organs, is so much less than mercury in relation to their spirocheticidal amounts that sufficient amounts for curative purposes can be ordinarily maintained in the blood for longer—much longer—periods of time without injury to the excretory or other organs.

But how then does mercury exert curative effects in syphilis?—and no one can deny that this occurs. As previously stated, I believe spirocheticidal effects are due to the mercury ions and that mercury accumulates in syphilitic tissue to a greater extent than in non syphilitic tissue. In other words, I believe that mercury has a greater affinity for *Spirochæta pallida* and the inflammatory exudates engendered by it than it has for non-infected tissues, and that during the administration of mercury it tends to accumulate in the infected tissues, soon reaching a concentration sufficient for spirocheticidal effects. The finding of such large amounts of mercury in an aneurysm of a syphilitic individual by Mastin and myself, previously referred to, has greatly influenced me to the opinion that mercury tends to accumulate in syphilitic tissues; of course, a portion is eliminated, but when mercury is administered

by mouth, inunction or by intramuscular injection it is easy so to regulate the dosage that accumulation to therapeutic concentration occurs in the infected tissues without toxic effects upon the kidneys, liver and other organs.

Just how mercury kills spirochetes after being brought into contact with them is unknown. It may be that the ions united with the proteins of the parasites brings about precipitation and death, but the exact mechanism of destruction is as obscure as the general subject of the destruction of parasites by germicides.

Other Pharmacological Effects of Mercury.—Very few studies have been made on the pharmacological actions of mercury beyond the subjects of absorption and elimination because the subject has not proven of much clinical interest. Dreser[29] studied the action of various compounds of mercury on the isolated heart and more recently Mueller, Schoeler and Schrauth[30] have reported experiment on the effects of several organic preparations on the circulation and respiration in cats in which injection was made intravenously. Salant and Kleitman[31] have carried out experiments with compounds of mercury on different animals and on the isolated heart of the dog and turtle. They also studied the effect of different substances on the action of mercury, giving some attention to its absorption from the small intestine and when given by intramuscular injection. The reaction of the rabbit to mercury was qualitatively the same as that of dogs, but their experiments indicated that rabbits could tolerate larger amounts of mercury than dogs.

In brief, mercury was found highly toxic to the heart, causing various cardiac irregularities, such as heart block, delirium cordis and finally paralysis. It is also toxic to the respiration, but the effect in this case is not nearly so pronounced as on the circulation. Furthermore, the action of mercuric salts may be greatly increased by citrate or by epinephrin, suggesting that under certain conditions associated with disturbances of metabolism the toxicity of mercury may be still more increased.

CHAPTER LIII

TOXICOLOGY OF MERCURY IN RELATION TO METHODS OF ADMINISTRATION AND THE TREATMENT OF SYPHILIS

Since mercury has been used and abused for centuries in the treatment of syphilis, it is not surprising that a great deal has been written on the toxicological effects and especially from the clinical standpoint. While threatened for a while to be displaced by arsphenamin and its substitutes in the treatment of syphilis, I believe that we may still agree with Fournier that "the position which it has attained in therapeutics after so many vicissitudes will always be maintained, for it has a powerful action on the disease—an action which has been disputed, but which is confirmed by all evidence, and cannot be ignored." But "the public of to-day bears malice against mercury in remembrance of the past" because of its toxic effects, especially stomatitis and salivation, resulting from errors in its administration, so that a thorough knowledge of its toxicological action in relation to methods of administration is almost of as much importance to-day in the treatment of syphilis as before the discovery of arsphenamin.

Mercurial Compounds of Special Interest from the Standpoint of Toxic Reactions in the Treatment of Syphilis.—Our interest, therefore, is mainly confined to the toxic effects produced by mercurial compounds employed in the treatment of syphilis, rather than to mercury poisoning in general. Naturally a very large number of various soluble and insoluble salts have been described and employed for the treatment of this disease in the search of centuries for compounds less toxic, more therapeutic and more elegant than others. Within the last ten years more systematic researches have been made along the lines laid down by Ehrlich in the development of the chemotherapy of the organic arsenical compounds in efforts to evolve a compound of reduced toxicity for the host with enhanced destructive activity for *Sp. pallida*, but so far none have been produced approaching anywhere near arsphenamin and neoarsphenamin in these respects. As a result, however, a very large number of new organic mercurial compounds have been produced, a recent excellent bibliography of the literature of which has been published by Whitmore.[1] From the standpoint of the treatment of syphilis and bacterial infections such compounds as asurol, mercurophen, flumerin, mercurochrome and mercurosol represent distinct advances, but so far no one has yet succeeded in evolving a mercurial compound possessing a chemotherapeutic index for *Sp. pallida* approaching that of arsphenamin.

As will be shortly discussed, the chemical constitution of mercurial compounds influences their local and systemic effects quite considerably; for example, mercuric chlorid and the yellow iodid (protiodid) are more apt to produce gastro-intestinal irritation than mercury with chalk, and intra-

muscular injections of the former are quite painful, because the soluble inorganic mercuric salts in general are especially irritating. It would lead me too far afield to discuss in detail even a small proportion of the large number of soluble and insoluble inorganic and organic compounds advocated from time to time for the treatment of syphilis; it is sufficient to concentrate on such compounds as the bichlorid, protiodid, succinimid, salicylate, calomel, the metal itself in various preparations and a few of the newer compounds as mercurophen, flumerin and mercurosol. In the treatment of syphilis mercury may be administered by four different routes, namely, by injection, by cutaneous application, inhalation and by ingestion; but different compounds vary in their toxic and therapeutic effects according to the route of administration, although the main lesions and systemic effects are essentially similar.

Chemistry of Mercurial Compounds in Relation to Toxicity and Therapeutic Activity.—Despite a great deal of research in the chemotherapy of mercurial compounds, no rules or definite "leads" have been discovered for establishing a relation between chemical constitution and biologic effects. Indeed, very little advance has been made in this field; it is true that new compounds of greatly reduced toxicity have been produced in the past few years, but these are likewise of reduced therapeutic activity or toxicity for the parasites. The triumph of arsphenamin was the discovery of a compound of reduced toxicity for the host with increased toxicity for the parasite, but similar results have not yet been achieved for mercury. If we could reduce the toxicity of mercury for the host without reducing at the same time its spirocheticidal activity or, if we could increase its spirocheticidal effects without at the same time increasing its toxicity for the host, a real advance would be made. Most investigators have sought to produce new compounds of lowered toxicity for the host of which flumerin is a striking example, but it is necessary to administer relatively large amounts for spirocheticidal effects leaving the chemotherapeutic index, which is the relation or proportion between the maximal tolerated and minimum curative doses, practically unchanged. In other words, compounds least toxic for the host are proportionately least toxic for spirochetes; simply because some compounds, as flumerin and mercurosal, can be given in larger doses because of reduced toxicity for the host does not necessarily mean that they are more curative in the treatment of syphilis, athough it may mean that such are less likely to produce local irritation of the muscles, gastro-intestinal tract, etc.

Therefore, we do not yet know how to increase the spirocheticidal activity of mercury while reducing its toxicity for the host or keeping this action unchanged. Stimulating and promising efforts have been made, however; for example, in 1912 Blumenthal and Oppenheim[2] reported work offering considerable encouragement along these lines, although in some respects it has not been generally confirmed by Kolle and others. Blumenthal and his associates believed that the chemical constitution of mercury compounds influenced their affinity for the tissues in that the aromatic compounds behaved in the body according to whether the mercury was bound to the radicle by one or two valences. Ionizable compounds showed, according to their experiments, a distinct affinity for the liver but not for other organs; colloidal mercury lacked this hepatotropism. Mercury bound by two valencies, as the sodium salt of di-amino-mercuri-diphenyl-di-carbonic acid, did not show any tissue affinities and was but slightly toxic and compounds in which the two amino groups were replaced by nitro or hydroxyl groups were found to circulate for some time in the blood with final localization in the liver. The amino groups, therefore, were believed to hinder the deposition

of mercury. The introduction of iodin or bromin decreased rather than increased tissue affinity. None were found to have any special affinity for the central nervous system, which lead them to believe that the curative activity of mercury in neuro-syphilis is not due to any special affinity for these tissues but rather depends upon the localization of mercury in the liver with the production there of new spirocheticidal substances. I cannot agree with these latter propositions, for there is little or no histological evidence to show that the compounds of proven curative activity in syphilis have any special affinity for the liver; on the contrary, I believe that mercury does have a special affinity for syphilitic tissue in general regardless of the organ involved.

But if we are still in the dark regarding the chemistry of mercurial compounds insofar as influencing separately toxicity for the host (organotropism) and toxicity for the parasites (parasitropism), what do we know of chemical laws by which toxicity for both host and parasites may be increased or decreased together even though we cannot greatly influence them separately?

Does solubility exert an influence? In a broad and general manner, compounds soluble in water or weak alkaline solutions are more toxic than those that are insoluble; but many of the latter are soluble in the tissues, which tends to reduce the differences. Likewise some of the soluble compounds, like the bichlorid, are more irritating to the tissues; but this is not always the case as shown by the lesser irritating effects of such soluble compounds as mercurophen, mercurochrome, flumerin and mercurosal. Solubility, therefore, is not of itself a criterion of either increased or decreased local and systemic toxicity for either host or parasite, but when considered in relation to mercury content and, more especially, the rate of dissociation of mercury ions in the tissues, solubility is a matter of importance in that soluble compounds of readily ionized mercury are more toxic than insoluble compounds of slowly ionizable mercury.

Does the content of mercury exert an influence? In other words, are those compounds containing most mercury proportionately most toxic and most spirocheticidal? In a broad and general manner, this is true as shown by the investigations of Schamberg, Raiziss and myself shortly to be reviewed, but *only when the compounds are of the same class in relation to solubility and the rapidity with which the mercury is dissociated in the tissues.* For example, the cyanid of mercury containing 79 per cent. of mercury is more toxic than the succinimid containing 50 per cent., because the former contains more mercury and because both belong to the same class of compounds insofar as solubility and the rate of dissociation of mercury in the tissues are concerned.

Does the rate of dissociation or ionization of the mercury in the tissues exert an influence? In other words, are those compounds in which the mercury is firmly bound to the organic radical less toxic than those in which the mercury is quickly dissociated? In 1911 Muller, Schoeller and Schranth[3] showed that those organic compounds in which the mercury was very firmly bound to the organic radicle, as in the case of Pesci's mercury di-benzoic acid, were much less toxic than compounds in which the mercury was less firmly bound; they stated that the effects of mercury set in as the mercury is split off and that the intensity of action depends on the readiness of this liberation and on the rapidity with which the molecular form is excreted. On this basis they divided the mercury compounds into (*a*) the inorganic, in which dissociation is rapid; (*b*) the pseudo-complex, in which dissociation is less rapid; (*c*) the half-complex, in which ionization or dissociation is still less rapid, and (*d*) the full-complex, in which each valence of mercury is so firmly bound to an organic radical, that dissociation is very slow or does not occur at all before the compound is excreted unchanged and practically inert. Therefore,

inorganic compounds would be most toxic followed in order by pseudo-complex, half-complex and full-complex compounds, the latter being almost free of toxicity or rapidly eliminated before dissociation of mercury occurs. Abelin found the aromatic compounds less toxic and Tuwtsungming[4] observed that the *local* irritation is strongest with the inorganic compounds while *systemic* toxicity is likewise highest for inorganic mercuric salts, next with the organic compounds and least with the mercurous salts, in general confirmation of the claims made by Muller and his associates; Schrouth and Schoeller[5] believed, from their studies of a large number of mercury compounds, that the therapeutically active substances are to be found in the class of half-complex compounds because in the full-complex compounds the mercury is dissociated so slowly as to render them inert and in the pseudo-complex and inorganic compounds, dissociation occurs so rapidly as to render them too highly toxic.

Kalges and Schreiber,[6] however, state that the toxicity and spirocheticidal (for *Sp. gallinarum*) effects of the mercury-dye compounds bears no relation to mercury content or rate of dissociation. Kolle and Rothermundt[7] have expressed the same opinion after experiments with "asurol," dinitro-mercuri-diphenyl-carboxylic acid, "argulan," sulfamino-antipyrene mercury, and other compounds in the treatment of hen spirillosis (*Sp. gallinarum*), stating that the therapeutic value of mercury compounds bears no relation to mercury content, rate of dissociation of mercury or solubility.

But I am of the opinion that the rate of ionization or dissociation of mercury is of considerable importance in determining both toxicity for the host and toxicity for the parasites (spirocheticidal activity). Apparently ionized mercury is equally toxic for both and compounds which are absorbed and eliminated unchanged are apt to be the least toxic and least therapeutic. Without dissociation or ionization no chemical action can occur and the compound is inert. Rapidly ionized compounds like mercuric chlorid are most toxic for the host and parasites and likewise most toxic by local contact with the tissues when injected subcutaneously and intramuscularly or applied to mucous membranes, as when administered by ingestion. The chemical properties of the ionizable mercurial compounds are largely produced by the ions they liberate on dissociation and as a consequence the physiological effects of electrolytes are due to their ionic state and through the ions that are present in a cell many of its chemical processes are controlled. Furthermore, chemical constitution may control the rate and degree of dissociation and ionization of mercurial compounds. The salicylate of mercury, for example, owes its popularity in the treatment of syphilis largely to the fact that it produces but little pain and local reaction when injected intramuscularly because of its half-complex chemical constitution, as a result of which the mercury is dissociated and ionized slowly and, indeed, a portion of the substance may be absorbed and eliminated unchanged. It is an anhydrid of ortho-oxy-mercuri-salicylic acid in which only one of the two valencies of the divalent mercury has been connected to the carboxyl of the acid. The other one is directly connected to the carbon of the benzene nucleus which results in a compound very difficult of dissociation and ionization. Of course, when injected intramuscularly, dissociation slowly occurs because toxic effects and curative activity are apparent in the treatment of syphilis, but evidently the rate of ionization is slower than in the case of calomel and probably of gray oil as well. As stated above, we have not yet discovered a means for increasing or decreasing the toxicity of either separately, but the firmness with which the mercury is bound in the molecule exerts an influence upon the rate and degree of ionization which influences both toxicity and therapeutic activity.

In my opinion, solubility in the tissues, percentage of mercury and rate of dissociation of mercury influence toxicity and therapeutic activity. The least toxic compounds are those which are insoluble and contain small amounts of mercury in which the mercury is firmly attached and almost non-ionizable; the most toxic are those which are soluble and contain large amounts of quickly ionized or dissociable mercury. Between these extremes are many compounds. Flumerin, the disodium salt of hydroxy-mercuri-fluorescein, is soluble, contains 32.5 per cent. of mercury but is at least 15 times less toxic than mercuric chlorid containing 74 per cent. of mercury; the difference in toxicity is not due to solubility, as both are readily soluble, but to the differences in mercury content and to the fact that the mercury in flumerin is less readily dissociated. Mercurosal, di-sodium-hydroxy-mercuri-salicyl-oxy-acetate containing 43.85 per cent. mercury is 7 to 10 times less toxic than mercuric chlorid, not because of solubility, since both are readily soluble but to the fact that the latter contains less mercury and because the mercury is bound slightly more firmly in the molecule.

This brief review shows, therefore, that the chemistry of the mercurial compounds employed in the treatment of syphilis materially influences their local and systemic effects. Soluble inorganic compounds like the bichlorid are the most toxic because readily dissociated; therefore, they are likely to be the most irritating when applied locally, injected intramuscularly or injected intravenously. They are most rapid in union with proteins and, therefore, most bactericidal, most corrosive and most likely to produce intravascular hemolysis and plasma precipitation. Soluble organic pseudo-or half-complex compounds, like the succinimid, flumerin and mercurosal, are less toxic because less readily dissociated, less bactericidal, less corrosive, and much less likely to produce intravascular reactions. For the same reasons they are likely to be somewhat less spirocheticidal, although the differences are more difficult to elicit because variations in curative activity in human and experimental syphilis are more difficult to express in well-defined terms and figures than is toxicity.

Toxicity of Mercurial Compounds for the Lower Animals in Relation to Toxicity for Human Beings.—We may now briefly review the results of toxicity tests employing the lower animals and the mercurial compounds commonly employed in the treatment of syphilis; these are not without some interest and practical importance in relation to the treatment of this disease.

These results are probably best expressed according to the *maximum single tolerated doses per kilo of body weight* by intravenous and intramuscular injections. In 1915 Schamberg, Raiziss and I[8] observed the following results with soluble salts, employing white rats injected intravenously:

Compound	Per Cent. Hg	By Intravenous Injection	By Intramuscular Injection
Mercury bichlorid	74	0.002	0.0065
Mercury succinimid	50	0.0018	0.014
Mercury benzoate	45	0.0024	0.0085
Mercury cacodylate	20	0.0045	0.018
Mercury salicylate	58	0.003	0.004
Mercury oxycyamid	83	0.001	
Mercury sozoiodolate	32	0.0022	0.012

In a general manner, the toxicity of these compounds, varied roughly according to the mercury content. The cacodylate was borne in the largest dose, but this was because the product which we used contained only 20 instead of the theoretical 42 per cent. of

mercury. Leaving out this compound, it is observed that the maximum single tolerated dose of these soluble compounds by intravenous injection was from 0.001 to 0.003 gm. per kilo corresponding to 0.06 to 0.180 gm. or 1 to 3 grains per 60 kilograms (approximately 132 pounds). By intramuscular injection the doses ranged from 0.004 to 0.014 gm. per kilo corresponding to 0.240 to 0.840 gm. or 6 to 14 grains per 60 kilograms or 132 pounds; toxicity by intramuscular injection was, therefore, roughly four times less than by intravenous injection.

With the insoluble compounds, as calomel, the salicylate and gray oil, the maximum single tolerated doses by intramuscular injection were found to be from 0.004 to 0.006 gm. per kilo corresponding to 0.240 to 0.360 gm. or 4 to 6 grains per 60 kilograms.

Mercurophen, the sodium salt of oxy-mercuri-ortho-nitro-phenol, containing about 45 per cent. mercury, is borne by white rats by intravenous injection in dose of about 0.008 gm. per kilo, according to tests made by Schamberg, Raiziss and myself.[9] This dose corresponds to 0.480 or about 8 grains per 60 kilos or 132 pounds.

Flumerin, according to White, Hill, Moore and Young[10] is tolerated by dogs and rabbits in dose of 0.030 to 0.040 gm. per kilo; I have confirmed these results, employing white rats. This dose corresponds to 1.8 to 2.4 gms. per 60 kilos or 132 pounds.

Mercurosal is reported to be borne by guinea pigs and dogs in dose of 0.025 gm. per kilo by intravenous injection, which corresponds to 1.5 gm. per 60 kilos or 132 pounds.

It is now interesting to note how the doses of these various compounds ordinarily administered in the treatment of syphilis compare with the maximum single tolerated doses (M.T.D.) for the lower animals; these may be expressed as follows in terms of the dose per 60 kilos or 132 pounds:

Compound (Intravenously)	Estimated Maximum Tolerated Dose	Estimated Dose for Treatment	Ratio
Bichlorid of mercury	0.120 gm.	0.01 gm.(1/6 gr.)	1:12
Succinimid of mercury	0.108 gm.	0.015 gm.(1/4 gr.)	1:7
Benzoate of mercury	0.144 gm.	0.01 gm.(1/6 gr.)	1:14
Cyanid of mercury	0.060 gm.	0.005 gm.(1/12 gr.)	1:12
Mercurophen	0.480 gm.	0.02 gm.(1/3 gr.)	1:24
Flumerin	1.8 gm.	0.18–0.3 gm.(3–5 gr.)	1:6 to 1:10
Mercurosal	1.5 gm.	0.1 gm.(2 gr.)	1:15
Mercurosal (Intramus.)	3.0 gm.	0.05 gm.(1 gr.)	1:6
Calomel (Intramus.)	0.3 gm.	0.06 gm.(1 gr.)	1:5
Salicylate of mercury (Intramus.)	0.3 gm.	0.06 gm.(1 gr.)	1:5

It will be observed from this summary that the dose of flumerin advocated for the treatment of syphilis (0.003 to 0.005 gm. per kilo) is only 6 to 10 times less than the maximum tolerated dose; the dose of mercurophen which I employ is 24 times less, the dose of mercurosal for intravenous injection is 15 times less and the other compounds from 7 to 14 (average 12) times less than the maximum tolerated doses for the lower animals. These ratios are worthy of being kept in mind when comparing one mercurial with another in the treatment of syphilis; that is to say, when superior claims are made for a compound it is well to know how the dose employed compares with the maximum tolerated dose for the lower animals, since the effects may be due more to larger doses than to any superior spirocheticidal activity on the part of the drug.

From the standpoint of intramuscular injection, it will be observed, that according to established custom, the margin of safety is somewhat less since the doses ordinarily given are only 5 to 6 times less than the maximum tolerated doses for the lower animals.

These figures, however, do not tell the whole story of the comparative toxicity and merits of the different compounds as employed in the treatment of syphilis. For example, when given intravenously, they do not show the incidence of acute reactions of fever, vomiting, diarrhea, etc., as these effects

are not ordinarily elicited in the smaller lower animals. From this standpoint, mercurosal, flumerin, mercurophen and the succinimid are to be preferred as they do not precipitate the plasma proteins as may the bichlorid, cyanid and other salts and clinically are better borne. Likewise from the standpoint of renal irritation, marked differences are shown. In my experience the salicylate, succinimid, bichlorid and benzoate are more likely to produce nephritis of the lower animals than mercurophen, mercurosal and flumerin. From the standpoint of local irritation by the soluble salts injected intramuscularly, the bichlorid is probably most irritating and mercurosal the least; mercurophen is too painful for intramuscular injection and while flumerin is less so, it has not been employed in the treatment of syphilis by this route of administration. Of the insoluble compounds, calomel is most painful followed in order by gray oil, the salicylate and mercurosal.

Pathological Tissue Changes Produced by Mercurial Compounds in Relation to Toxic Reactions and the Treatment of Syphilis.—This naturally leads one to inquire regarding the chemopathological tissue changes of the internal organs that may be produced by the administration of mercury and especially how these vary or are influenced by different compounds and different routes of administration. It is generally well known that the kidneys are especially likely to suffer and that careful examinations of the urine are indicated during the treatment of syphilis for evidences of renal irritation, but the possible changes in other organs are not without interest and importance.

Studies of this kind are best made with the lower animals because human tissues obtained at necropsy are always likely to show the presence of lesions produced by syphilis or other diseases apt to be confused with those that may be produced by mercury. In 1915 I made a study of the kidneys of rabbits treated with intravenous and intramuscular injections of various salts and well-defined tubular and diffuse lesions were observed which bore some relation to the kind of compound injected, the percentage of mercury contained and the duration of life. A few reports are to be found in literature bearing on the nephritis produced by mercuric chlorid; excellent studies of experimentally produced nephritis have been made by Elbe,[11] Burmeister and McNally[12] and MacNider.[13] These investigators have considered the kidney lesions dependent on the action of the mercury on the vascular tissues of the kidney, to the action of the metal as such on the parenchyma during elimination or to shock associated with severe mercury enteritis and the development of acid intoxication.

In 1921 Lucke and myself[14] made a rather extensive study of the histopathological changes produced by different mercurial compounds administered to rabbits by intravenous and intramuscular injection, by inunction and by ingestion; as expected, individual animals exhibited varying degrees of tissue injury, so that a comparison of the kind and severity of the lesions produced by the different preparations of mercury administered by different routes, in multiple small doses, is possible only in a broad and general manner.

The lesions produced by the different mercurials were quite similar and may be briefly summarized for the different organs as follows:

The *brain and meninges* showed an interesting and unexpected perivascular round-cell infiltration; curiously, this change is regarded as more or less constant in syphilitic infection of these tissues, and our findings quite naturally raised the question of the significance of perivascular round-cell infiltration in the brain of syphilitic subjects who have taken mercury during life. Among the animals receiving a large amount of mercury, some conges-

tion and edema with slight perivascular round-cell infiltration were noted in the pia mater. These lesions were somewhat more marked in animals which received intramuscular injections. In view of the unexpected finding of perivascular round-cell infiltrations in the brains of some of these rabbits and their practical importance in relation to similar changes produced by syphilis in the central nervous system and especially in paresis, we continued this study[15] with monkeys in view of the report by Oliver,[16] that spontaneous meningeal and cerebral lesions of perivascular round-cell infiltrations may be found in normal stock rabbits. Preliminary to this study, however, Lucke[17] examined the brains from monkeys which had died at the Philadelphia Zoölogical Garden with the result that the brains of nine animals were found to show pathological changes of non-suppurative meningo-encephalitis, arteriosclerosis with focal necroses and gliosis, etc., but with no tissue changes exactly similar to those apparently produced by mercury. Three monkeys, in good condition, were used; the first received 37 inunctions of blue ointment in dose equivalent to 4 gm. per 60 kilos at the rate of three per week; the second received 37 intramuscular injections of mercuric chlorid in dose of 0.02 (⅓ grain) gm. per 60 kilos at the rate of three per week and the third received 14 intramuscular injections of salicylate of mercury in dose of 0.06 (1 grain) gm. per 60 kilos at the rate of one per week. The histological changes were summarized as follows: (1) The pia-arachnoid was locally thickened and cellular; this was most pronounced in the sulci and was chiefly due to fibroblastic hyperplasia. (2) The endothelium of many capillaries and of the small vessels in general was large and swollen and in a state of active proliferation. New vessel formation, as evidenced by capillary budding, was frequently observed. (3) A mild and nowhere striking infiltration of the adventitial lymph space of the smallest vessels with lymphocytes, plasma cells, and intermediate forms was present. (4) There was a moderate proliferation of the cellular as well as the fiber-forming neuroglia. The former was most distinct about proliferating capillaries, in the white matter and in the neighborhood of diseased ganglion cells; the latter was best seen in the subependymal and marginal cortical layers. (5) A relatively small number of ganglion cells were in a state of acute degeneration. (6) The distribution of the lesions mentioned was irregular, mainly local in character, and on the whole most pronounced in the basal portions of the brain.

The lesions described affected chiefly the capillaries and small vessels; they were proliferative, degenerative and mildly exudative in character; they, therefore, correspond to our conception of a reaction to an irritant. A comparison with the tissue alterations occurring in the central nervous system after intoxication with two other metallic poisons, lead and arsenic, discloses an essential similarity. The neuropathologic picture of arsenical poisoning has been described by Jacob, Weygand and Kafka;[18] these observers injected solutions of arsphenamin and neoarsphenamin into the central nervous system of monkeys. The changes of lead encephalopathy have been recently summarized by Hassin,[19] who confirms the results of similar studies by Mott[20] and Bonfiglio.[21] Hassin showed that lead and arsenic induce nervous changes that may be designated as toxic nonsuppurative encephalitis. As examples of the latter group, epidemic encephalitis and poliomyelitis may be mentioned; in these infections infiltrative and exudative phenomena characterize the picture, while proliferative alterations preponderate in the toxic group.

While we are in general accord with Hassin's statements, it seems to us, however, that the lesions of certain chronic infections (i.e., syphilis) are more

difficult to separate from the infectious type mentioned above, for in syphilis proliferative changes are as prominent as, if not more prominent than, degeneration and exudation. In dementia paralytica, which is universally regarded as due to syphilis, the histopathologic picture consists essentially in new vessel formation, marked swelling of the vascular endothelium, infiltration of the adventitial spaces and the nervous parenchyma by certain round cells probably derived from the blood or lymph stream, the occurrence of rod (Stabchen) cells, proliferation of the neuroglia of all types, and various degenerative changes of the ganglion cells and other structures. The lesions of general paralysis are most commonly confined to the frontocentral parts of the cerebral hemispheres, but cases occur in which other parts of the brain are more involved.

Now these changes of general paralysis are, in their essential nature, similar to those we have just described as resulting from experimental mercurial administration. In point of severity, however, the lesions due to mercury are far less intense.

While there can be no doubt that syphilis is the essential cause of general paralysis, it is still an open question whether other factors, among them mercury, arsenic, or other metals, may not play a subordinate rôle in the establishment of this entity. It must be distinctly understood, however, that no evidence has as yet been adduced that any of the clinical manifestations of general paralysis are due to mercury. We do not wish to be understood as putting forth the claim that mercury is responsible for the principal lesions of general paralysis, but, in view of our experimental results in monkeys, we feel justified in asserting that this metal and possibly other organic poisons may produce structural alterations of sufficient degree to influence the histopathologic picture. In this connection it is well to bear in mind that the salts of mercury (as well as those of arsenic and lead) produce tissue changes in many organs (kidneys, liver, gastro-intestinal tract, etc.), and that the mercurials in particular call forth distinct alterations in the blood-capillary system. It would be remarkable if the nervous tissue should be exempted.

As a general rule, the *heart* showed no changes although in those animals receiving the maximum amounts of mercury there were evidences of slight focal necrosis of the muscle cells with intermuscular round-cell infiltration.

Changes in the *lungs*, when found at all, mainly consisted of congestion and slight edema.

The changes found in the *spleen* consisted mainly of hyperemia and hemosiderosis, apparently due to increased blood destruction.

Changes in the *liver* were usually inconspicuous and when noted at all comprised congestion, filling of the sinuses with partially hemolyzed erythrocytes and hemosiderin staining of neighboring hepatic cells. In some animals there were evidences of slight cloudy swelling of the hepatic cells and slight perilobular fibrosis.

The *kidneys* have shown the most conspicuous changes analogous to those previously described by me and every one showed some degree of tissue injury, the severity varying considerably according to the amount of mercury administered. The most constant lesions were found in the tubules characterized by cloudy swelling, fatty degeneration, frank necrosis, calcareous infiltration and the presence of large numbers of casts. The convoluted tubules suffered most; the limbs and loops of Henle were sometimes involved while the collecting tubules generally escaped. The glomeruli were sometimes hyperemic and among animals receiving the larger amounts of mercury, granular exudates occurred in the capsular spaces. Among the animals

surviving for the longer periods of time, there were evidences of repair of the tubular cells accompanied by interstitial changes of lymphocytic infiltration and fibrosis.

As far as we could ascertain, with hematoxylin and eosin-stained sections, the *suprarenal glands* showed no changes, although we reported reservedly on the histology of these tissues in this series of experiments.

Relation of the Kind of Compound of Mercury and Route of Administration to Tissue Injury.—In-so-far as the kind of compound in relation to tissue injuries is concerned, it may be stated that the lesions were essentially similar and bore a rough relation to the amounts of mercury administered in the various compounds. This is to be expected, as the mercury of the compounds employed is readily dissociated and I believe the tissue injuries are due primarily to ionized mercury regardless of the kind of compound from which it is derived. Therefore, compounds of the half- and full-complex type are least likely to produce tissue injury because they may be eliminated unchanged before dissociation or ionization can occur; soluble inorganic salts like the bichlorid, on the other hand, are apt to produce severe changes because the mercury is so quickly dissociated. When compounds of mercury are injected intravenously, however, we may produce acute changes in the blood due to variations in hydrogen ion and other physical phenomena produced by the compound in addition to those produced by the dissociated mercury.

The route of administration bore a more definite relation to the pathological tissue changes. Apparently ingestion produces the mildest changes, but the liver may be particularly involved. Intravenous injections of the soluble salts produced the severest changes, followed in order by intramuscular injections of the soluble salts, intramuscular injections of the insoluble salts and inunctions. Doubtless the degree of solubility and rapidity of absorption were the determining factors.

Of special interest in this connection is the question of absorption of calomel applied by inunction. Schamberg, Raiziss and I have found that absorption occurred when calomel was applied to the skin of rabbits, but Cole and his associates found that calomel inunctions produced much less salivation than inunctions of blue ointment, and on this basis expressed the opinion that absorption was much slower and less certain. But I am convinced of the absorption and therapeutic effects of calomel inunctions. The ordinary blue ointment is 50 per cent. of mercury; since calomel contains less mercury, it should be used in 85 per cent. ointment. Recently Cole, Hutton and Sollman[22] have advocated a clean inunction treatment of syphilis consisting in the usual daily inunctions of 4 gm. of blue ointment (50 per cent. mercury) rubbed in for thirty minutes, followed by washing the skin with benzene. They claim that the results are just as good as when the ointment is left on the skin over-night as is the usual custom. But I have found in experiments with rabbits that washing off the excess with benzene greatly reduces the degree of absorption. For example, rabbits of 1800 to 2000 gms. rubbed daily for 30 minutes with 0.5 gm. of blue ointment usually lose rapidly in weight and die with nephritis after 6 to 10 doses; rabbits rubbed in exactly the same manner, for the same length of time, but washed off with benzene and placed in a separate room, stand 8 to 12 doses. Rabbits rubbed for 30 minutes with 0.5 gm. of 85 per cent. calomel ointment usually lose rapidly in weight and die with acute nephritis after 3 to 5 doses; rabbits treated in exactly the same manner but washed with benzene and placed in a separate room, stand 8 to 12 doses. Experiments of this kind have convinced me, therefore, of two things, namely, (1) that calomel applied

by inunction is absorbed and (2) that absorption of both calomel and blue ointment is greater (probably by volatization and inspiration) if the excess is allowed to remain on the skin.

Local Tissue Changes Produced by Intramuscular Injections of Mercury. All compounds of mercury injected intramuscularly produce varying degrees of local tissue reaction. By injecting small doses into the thigh muscles of the rabbit, guinea-pig or rat, in exactly the same area, and carefully excising the tissues five days later, it was possible by means of serial sections to study the kind and degree of changes produced by different compounds injected in water and oils. I have made a study of this kind with mercuric chlorid,

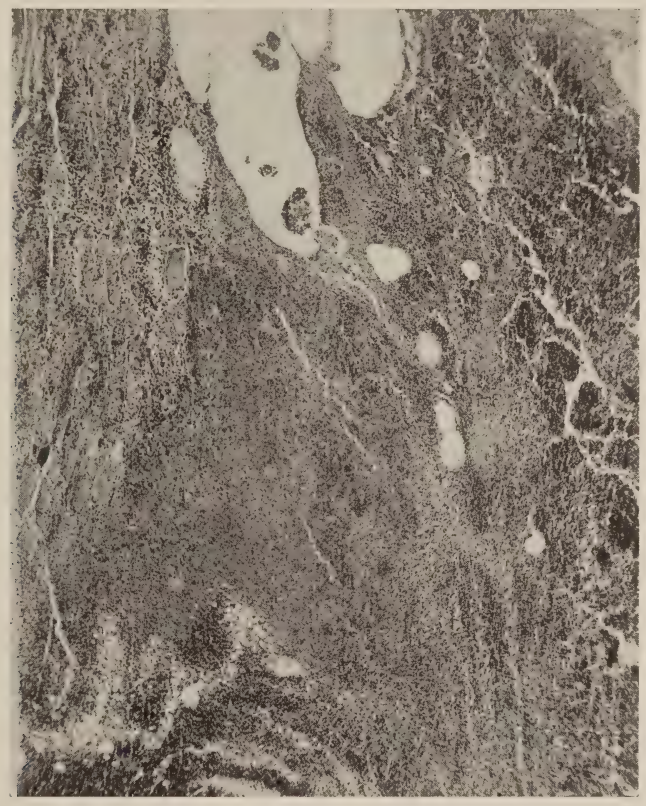

FIG. 25.—LOCAL REACTION PRODUCED BY INTRAMUSCULAR INJECTION OF SALICYLATE OF MERCURY.

Injection of 0.1 gm. in olive oil (4 days).

mercurophen, mercurosal, calomel, salicylate and gray oil with rather interesting and practical results which are here briefly summarized.

In the first place the essential tissue changes are the same for all compounds and consist of varying degrees of muscle necrosis with leukocytic infiltration, edema, congestion and fibrosis. All of the compounds studied produced reactions, the severity varying, of course, with the amounts injected (0.002—0.1 gm.). The degree of muscle necrosis, however, was less than produced by the organic arsenicals. The infiltrations were composed mainly of polymorphonuclear leukocytes followed by lymphocytes, plasma cells and fibroblasts (Fig. 25).

Soluble compounds usually produced a somewhat sharper reaction than insoluble compounds, that is, there was more necrosis of muscle, denser leukocytic infiltration, more congestion and hemorrhage and more edema. I presume that these changes were due primarily to the degree and rapidity of dissociation of mercury, since compounds of the inorganic class, like the bichlorid, which dissociate rapidly, produced more reaction than organic compounds like the salicylate and flumerin which dissociate more slowly and, indeed, may be absorbed and eliminated in part without any dissociation at all.

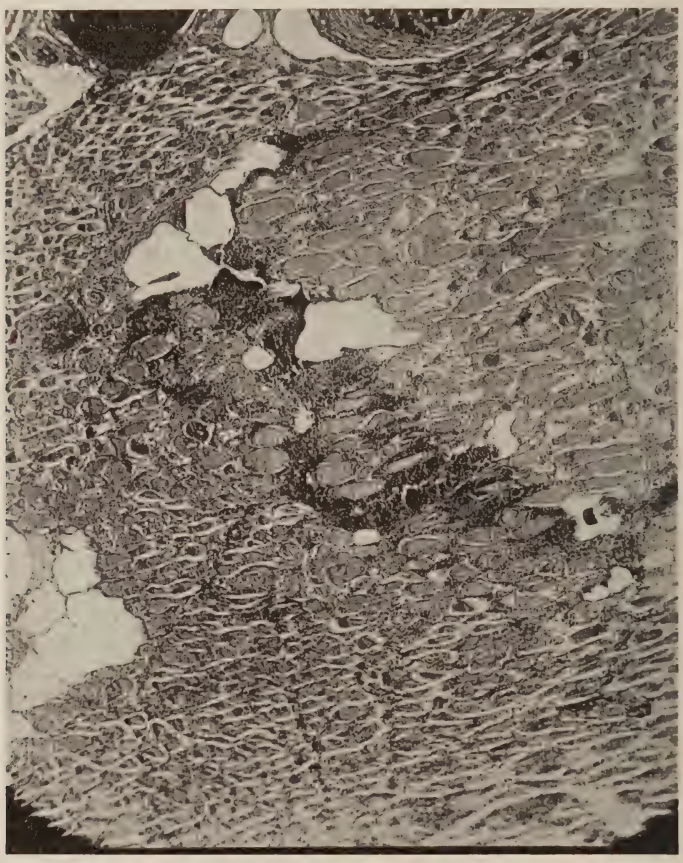

FIG. 26.—LOCAL REACTION PRODUCED BY INTRAMUSCULAR INJECTION OF CALOMEL IN OIL.

Injection of 0.002 gm. in olive oil (5 days).

Insoluble compounds produced less reaction than soluble compounds, but these varied somewhat in this relation; suspensions of calomel for example, produced more reaction than suspensions of the salicylate or gray oil, but I believe that these differences were due primarily to variations in the rapidity of dissociation of the mercury ions.

The menstrum employed modified the local reaction to a considerable extent. For example, bichlorid in water produced a sharper reaction than a similar dose in almond oil; suspensions of the salicylate in water produced sharper reactions than suspensions in oil, etc. The lesions produced by

suspensions in almond or olive oils were actually somewhat larger, but this was due to the fact that they were less circumscribed, that is, the leukocytic and serous infiltrations were more diffuse than produced by water solutions or suspensions. Suspensions in almond or olive oils were more diffuse than suspensions in paraffin oil; the latter were more circumscribed with sharper encapsulation.

It was apparent, therefore, from these histological studies, that the *degree* of local intramuscular reaction produced by injections of mercury compounds varied according to solubility, dose in terms of mercury, rapidity of dissocia-

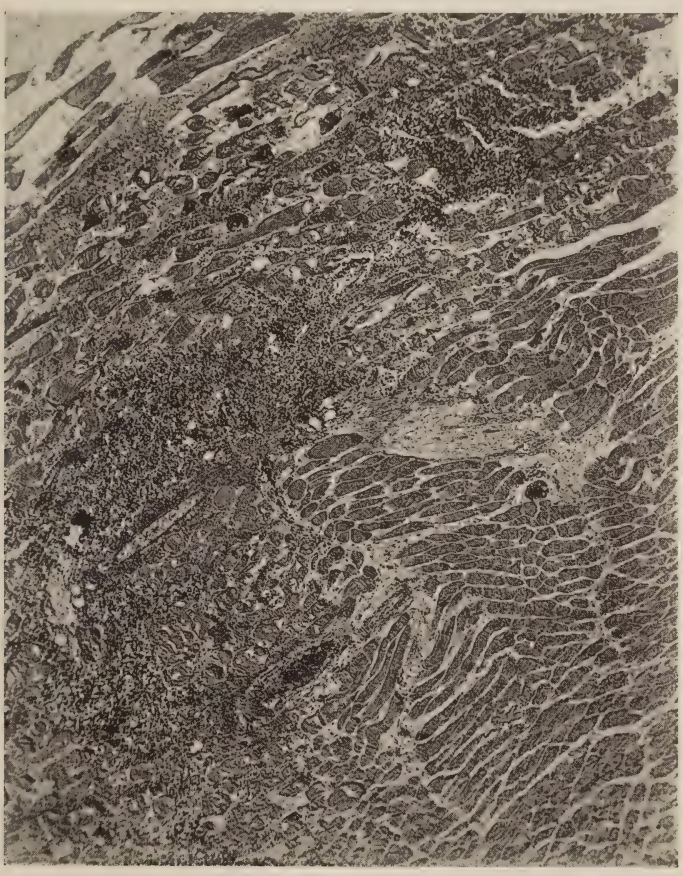

FIG. 27.—INFLUENCE OF POTASSIUM IODID UPON THE LOCAL REACTION PRODUCED BY THE INTRAMUSCULAR INJECTION OF CALOMEL.

Injection of 0.002 gm. of calomel in olive oil following the oral administration of potassium iodid for five days.

tion of mercury ions and the menstrum employed. Soluble inorganic salts of rapid ionization, like mercuric chlorid, administered dissolved in water, produced the most severe but sharply localized lesions; when administered in almond oil the reactions were less severe in the sense that they were more diffuse. Soluble compounds of slower ionization, as flumerin and mercurosal, produced somewhat less severe changes. Insoluble compounds suspended in vegetable oils varied, more reaction being produced by calomel and the metal itself (gray oil) than by the salicylate. Solutions or suspensions in water,

therefore, are apt to be more painful than suspensions in oil and suspensions in sterile almond or olive oils are to be recommended from this standpoint as preferable to the former.

In additional experiments, the drugs were injected intramuscularly to animals previously receiving solutions of sodium or potassium iodid by stomach tube for five or more days. This appeared to increase the degree of leukocytic infiltrations for all compounds as shown in (Figs. 26 and 27) as examples of the series. I do not know whether or not this possesses clinical significance, as I have not been able to satisfy myself that intramuscular injections of the salicylate, calomel or gray oil produced any more severe reactions among patients taking 10 to 30 grains of sodium or potassium iodid per day than among patients who were not taking the iodids, but these experimental studies indicated that, in a general way, the iodids tended to increase the degree of leukocytic reaction around the deposited drugs in the muscles of the lower animals.

Etiology and Mechanism of Toxicological Reactions Produced by the Administration of Mercurial Compounds. *Etiological Classification of the Toxicological Effects of Mercury Compounds.*—Upon first thought it would appear a relatively simple matter to explain the mechanism of the poisonous action of mercury upon the proposition that the metal united with cells and brought about their dysfunction or destruction. But the subject is not quite so simple and several additional factors require consideration. In the first place we must distinguish between those effects produced by the metal itself upon the tissues and the secondary effects following these; for example, McNider[23] believes that the kidney lesions in acute mercuric chlorid poisoning are not due to the action of mercury as such upon the blood-vessels and epithelium of the kidneys, but to the effects of acid intoxication resulting from the primary corrosive gastro-enteritis produced when the drug is swallowed. Furthermore, I believe that a distinction should be made between the effects of compounds of mercury and mercury itself and especially when injected intravenously.

These various factors may be classified, somewhat as follows:

Primary factors	(1) Corrosive local effects.
	(2) Degenerative effects of the compounds or of mercury itself upon the internal organs.
	(3) Effects of mercury upon the nervous system.
	(4) Hemolysis.
	(5) Precipitation of plasma proteins.
	(6) Acid intoxication.
Predisposing factors	(1) Hypersensitiveness to mercury.
	(2) Bacterial or spirochetic gingivitis; focal infection.
	(3) Gastro-intestinal, renal, hepatic and cutaneous disorders.
	(4) Syphilis (Jarisch-Herxheimer reactions).

Corrosive Local Effects of Mercury.—These refer to the local irritations produced when mercury is administered by ingestion, inhalation, inunction and by injection into the muscles, and they vary according to the compounds employed. By ingestion the inorganic compounds as a class are more irritating than the organic compounds and especially mercuric chlorid. The lesions are largely those of congestion, exudation and necrosis. In 1906 Schmiedeberg[24] expressed the opinion that the intestinal lesions were due to the destructive action of the metal during its elimination and Burmeister and McNally[25] later expressed a similar view. Mercury itself is not very irritating unless it becomes ionized, as shown by the old custom of administering very large doses for cathartic effects without injurious results, but I

have personally no doubt that quickly dissociated or ionized compounds produce direct corrosive effects before absorption, as shown not only by the rapidity with which gastro-enteritis follows the ingestion of large doses of mercuric chlorid, but also by the local tissue reactions produced when mercurial compounds are injected intramuscularly. Readily dissociated compounds, like the bichlorid and protiodid, are more apt to produce local irritation when administered orally, according to Fournier, than other compounds commonly employed in the treatment of syphilis; mercury with chalk on the other hand, is less corrosive and for this reason was the favorite of Jonathan Hutchinson. By inunction little or no differences are discernible but by inhalation, corrosive effects may be produced, more, however, by other chemical substances than by the metal itself, as shown by the disasterous effects of the old, obsolete and harbarous method of the treatment of syphilis by "perfumes."

Degenerative Effects of Mercury.—But are the lesions described above as occurring in the kidneys, liver, brain, heart muscle, etc., due to deposits of mercury in the cells, or, are they due to such secondary changes as disturbances in the acid-base equilibrium of the blood? In view of the fact that chemical analyses have regularly shown the presence of mercury in such organs, I believe that the lesions are due in most part to the necrosing or corrosive effects of mercury. Unfortunately, no thoroughly acceptable method has yet been evolved for demonstrating mercury in the cells by histological methods although Weidman[26] has worked out a method for demonstrating metallic mercury in the tissues as found by Mastin and myself in the tissues of an aortic aneurysm. I believe that ionized mercury is capable of union with cells and particularly of the kidney and intestinal mucosa and capable of producing degenerative lesions of cloudy swelling, liquefaction and coagulation necrosis followed by calcareous infiltration.

Mechanism of the Union and Action of Mercury upon Cells.—This raises the question of *how* mercury unites with cells and *how* it produces dysfunction and destruction. Unfortunately we possess no accurate information upon these subjects, but since the administration of sulphur compounds, as sodium thiosulphate, is said to reduce the toxicity of mercury, I surmise that mercury may enter into the protoplasm of cells by means of union with the sulphhydril group, as recently maintained by Voegtlin and his associates in the case of arsenic. Furthermore, it would appear as well established that larger doses of mercury are withstood and especially by inunction, when sulphur waters are freely taken internally as mentioned by Fournier in reference to the experience of Doyen at Uriage and as practiced at present at Aachen in Europe and at the Hot Springs of Arkansas in this country. How mercury interferes with the function of the molecule after this invasion has occurred is unknown; it may be by interference with sulphur metabolism, by coagulation of the proteins or possibly by interference with internal respiration by alternate oxidation and reduction. These are problems urgently requiring elucidation by pharmacologists.

Effects of Mercury upon the Sympathetic Nervous System.—Mercury undoubtedly may influence the nervous system and especially certain portions of the anatomic elements. Lesions of the peripheral nerves in the form of neuritis do not occur as frequently as in the case of arsenical and lead intoxications although tremors, irritability and rarely paralyses, may occur in chronic mercurialism. But in addition, mercury may influence the vasomotor system in a manner analogous to the action of arsenic but to a lesser degree, resulting in disturbances of blood-pressure and local lesions of congestion and edema, as seen in the changes of the tongue and buccal mucosa in

stomatitis, the skin lesions, etc. Furthermore, it would appear that the salivation of mercury without evidences of stomatitis may be due to a stimulation of the symphathetic nerves of the salivary glands, which explains in part the variations met with among human subjects in susceptibility to the salivating effects of this drug; furthermore, the increased output of urine sometimes associated with glycosuria, may be due in part to sympathetic nerve stimulation in conjunction with vasomotor changes.

Hemolysis and Precipitation by Mercurial Compounds Injected Intravenously.—Of further interest is the subject of the effect of mercury and mercury compounds upon the erythrocytes and plasma proteins. As discussed in Chapter XLV we have already shown that such intravascular reactions may be of considerable practical importance in relation to acute toxic reactions following the intravenous administration of arsphenamin and especially acid solutions.

Mercury itself in colloidal suspension does not hemolyse or agglutinate washed corpuscles or coagulate the plasma; neither do colloidal suspensions of calomel, although suspensions of the salicylate are actively hemolytic. But solutions of all of the soluble salts produce hemolysis and most of them precipitate plasma constituents. The degree of hemolysis, however, varies greatly with different compounds.

When tested in the presence of serum, however, hemolytic activity is greatly reduced, which of course reduces the significance to be placed upon the rôle of hemolysis in the production of acute reactions following the intravenous injection of mercurial compounds. Doubtless, however, a portion of the acute reaction following the intravenous injection of such a large dose of mercurochrome as 0.005 gm. per kilo in the treatment of local and general bacterial infections, is due to intravascular hemolysis.

Agglutination is not ordinarily observed; occasionally mercurophen may show slight agglutination in one or two dilutions higher than the hemolytic concentrations, but otherwise all of the soluble and insoluble salts of mercury fail to agglutinate even washed corpuscles which is in sharp contract with the high agglutinative properties of arsphenamin.

Practically all of the soluble mercurials will produce precipitates when added to serum or plasma in test-tubes. Mercuric chlorid is especially active in this particular, but the succinimid, mercurophen, flumerin, mercurochrome, and mercurosal do not, or, but to a minor degree, when very concentrated solutions are employed.

This is a subject, therefore, of some practical importance in relation to the choice of a compound for intravenous injection in the treatment of syphilis, because injections of such compounds which do not produce hemolysis or plasma precipitation as succinimid, mercurophen, flumerin, and mercurosal would appear to be indicated in preference to bichlorid, cyanid, benzoate, cacodylate and other soluble mercurials in order to avoid embolic reactions and infarctions. Of interest in this connection are the views of Heineke[27] and Kaufmann,[28] who believed that mercury in the blood had a thromboplastic action and that the damage to the kidneys depended upon the formation of thrombi with the production of infarcts.

Colloidal suspensions of mercury itself are likewise free of hemolytic and coagulating effects upon corpuscles and plasma and, contrary to what may be expected, do not tend to produce pulmonary embolism; this is especially true of the metal, which being labile, is able to slip through the capillaries of the lungs when the particles are not much larger than erythrocytes. Although the saliculate of mercury is not administered by intravenous injection, it is interesting to note in passing that it is quite hemolytic. The intravenous injection of coagulating mercurials, as the bichlorid, may excite a reaction of the character of the non specific protein reaction, possessing some therapeutic activity as claimed for mercurochrome in the treatment of local and general bacterial infections, but the doses required are very large in comparison with the maximum tolerated doses and the practice therefore is not devoid of considerable risk.

Just how hemolysis and plasma precipitation are produced is not definitely known, but I surmise that the effects are due to ionization of the mercury. The degree of activity of different compounds does not depend upon the content of mercury but salts of the inorganic acids are more active than those of organic acids. Therefore, compounds that are readily ionized are most active in these particulars and especially the soluble inorganic salts; half- and pseudo-complex compounds are much less active and full-complex compounds may be absorbed and eliminated before dissociation and these changes are produced at all.

Acid Intoxication in Relation to the Toxicology of Mercury.—As previously stated, MacNider has found that injury to the kidneys of dogs poisoned by mercuric chlorid has been constantly associated with the development of acid intoxication and that the delayed injury of these organs is due to this condition rather than to the action of mercury as such during its elimination. MacNider[29] has also found that in dogs with naturally acquired chronic-glomerulonephropathies, a state of acid intoxication is readily induced by chloroform and that this condition may be prevented by the intravenous injection of a solution of sodium carbonate equimolecular with a 0.9 per cent. solution of sodium chlorid. On the basis of these observations, Weiss[30] has developed an apparently successful treatment for acute bichlorid poisoning consisting of the internal and intravenous injection of sodium carbonate to which further reference will be made in this chapter in considering the treatment of mercurial poisoning.

Undoubtedly, this disturbance of the acid-base equilibrium is a very important facter in acute mercurial poisoning whether the drug is taken internally, is injected or is absorbed from the vaginal mucosa. Whether changes in the alkali reserve occur in milder forms of mercurialism, as in stomatitis and ptyalism, developing during the treatment of syphilis cannot be stated, but it is always my custom to administer sodium carbonate or bicarbonate internally in the treatment of such on the basis that minor disturbances of this kind may be present.

Hypersensitiveness to Mercury in Relation to Toxic Reactions.—As is now well known some individuals possess a high degree of natural hypersensitiveness to mercury and the merest contact with solutions of mercury may elicit in them severe reactions frequently expressed in the form of scarlatiniform eruptions. Others are rendered acutely ill, with vomiting, colic and diarrhea when taking internally even a fraction of the usual amounts of mercury, and it is believed that some of the fatal mercurial poisonings have occurred among hypersensitive individuals. In two cases that have come under my observation, skin reactions were elicited by the application of 1:100 solutions of mercuric chlorid to scratches on the arm.

Not infrequently one encounters syphilitic individuals who cannot tolerate mercury in any form by reason of nutritional disturbances, loss of weight, stomatitis, diarrhea, etc. These effects are probably due to lesser degrees of hypersensitiveness but when mercury is administered in any form it is well to observe closely for such symptoms in order to ascertain the individual tolerance. When administered intravenously not more than one tenth of the usual dose should be injected at first, in order to avoid or reduce what may prove to be serious and even grave reactions if the individual happens to be hypersensitive.

Whether or not hypersensitiveness is actually acquired during the prolonged administration of mercury in the treatment of syphilis cannot be stated. Not infrequently this condition appears to develop, but whether it is a true allergic hypersensitiveness or an intolerance due to accumulative toxic effects cannot always be determined or stated.

Gingivitis in Relation to Mercurial Ptyalism and Stomatitis.—Three of the most common toxicological effects of mercury are ptyalism, gingivitis and stomatitis. These effects are probably due to the excretion of the drug by the salivary glands and the buccal mucosa; stomatitis is especially likely to develop from inunctions, but most danger is from massive doses of the insoluble salts administered by intramuscular injection. It is a well established clinical fact, however, that pre-existing bacterial or spirochetic gingivitis greatly increases the incidence of ptyalism, siderosis (blue line), gingivitis and even of stomatitis following the administration of mercury. Just how these infections predispose is not definitely known, but probably by lowering resistance, interfering with elimination and by increasing the amounts of sulphur present with the production of mercury sulphid which is insoluble and irritating. Therefore, it is advisable and indeed imperative to inspect the gums of every patient about to start mercury medication and frequent inspections are required during its administration for siderosis, halitosis (foul breath), gingivitis and stomatitis, to which further reference will be made later in this chapter.

Whether or not focal infections at the apices of the teeth, in the accessory sinuses, the tonsils or elsewhere are important in relation to mercurial dermatitis and other toxic reactions, as believed by Stokes and others in relation to arsphenamin dermatitis, cannot be stated; but I believe that apical abscesses especially predispose the patient to mercurial gingivitis which in turn may readily enough favor the dissemination of bacteria from such foci so that I always insist upon a roentgenologic examination of the jaws for such foci as part of the preliminary hygiene of the mouth in preparation for the administration of mercury or bismuth.

Gastro-intestinal, Hepatic, Renal and Cutaneous Disorders in Relation to Mercurial Intoxication.—When mercury is administered by ingestion, it is particularly important that the gastro-intestinal tract shall be in a healthy state. Curiously while inunctions are especially apt to produce stomatitis, lower gastro-intestinal lesions and symptoms are much less likely to occur; Fournier states that inunctions rarely cause gastro-intestinal disturbances. It is a well-known clinical fact that the oral route of administration is unfavorable for those suffering with chronic gastro-intestinal, hepatic and gall-tract disease, not only because of the added corrosive effects of mercury, but because these organs are actively concerned in its elimination. Such individuals, therefore, are seldom fit subjects for mercury by any form of administration and least by ingestion; sooner or later their gastro-intestinal or hepatic symptoms are intensified with colic, diarrhea, a sub-icteric tinge of the skin and mucous membranes, loss of weight, etc.

Since mercury is so largely eliminated by the kidneys, there is risk in its administration if nephritis is present, not only because of the danger of interference of elimination with accumulative toxic effects, but because the degree of renal injury may be increased with the production of this vicious cycle of events. However, in syphilitic nephritis, the urinary changes sometimes improve under mercurial treatment, but it is a wiser plan to administer bismuth which is less renotoxic, or, better still, arsphenamin or neoarsphenamin, if treatment must be given. These cases represent some of the most difficult problems in the treatment of syphilis, but the order of drugs from the standpoint of least renal irritation are as follows: (*a*) the iodids; (*b*) arsphenamin and sulpharsphenamin; (*c*) neoarsphenamin; (*d*) bismuth and (*e*) mercury.

Skin lesions are of most importance in relation to inunctions of mercury. When the skin is very dry the epithelial cells are dried up, lose their resistance,

with the result that the sweat and sebaceous ducts are open and dry, as described by McConnell[31] in relation to the industrial dermatoses, permitting the greater absorption of mercury with more rapidly developing stomatitis and gingivitis as shown by Cole, Hutton and Sollmann.[32] Cole and Littman[33] have also recorded a case of severe mercurialism resulting from the rapid absorption of calomel ointment through superficial ulcero-crustaceous lesions of the skin of the entire abdomen.

Relation of Syphilis to Mercurial Intoxication and the Jarisch-Herxheimer Reaction.—Does syphilis alter susceptibility to mercury? I believe it undoubtedly increases tolerance for this drug in a most unmistakable manner in the majority of cases. Of course, susceptibility to mercury varies considerably among human beings and to a lesser extent among the lower animals, but the average tolerance of the syphilitic is higher than the average tolerance of the non-syphilitic healthy individual. One is frequently surprised with the large doses borne without any discernible ill effects by syphilitic individuals and especially in acute syphilis or very active tertiary syphilis as paresis. Kolle[34] states that syphilitic rabbits tolerate more mercury than normal controls per kilo of body weight, and, while I have not experimented along these lines, I am prepared to believe that it may be possible to define this increased tolerance of syphilized animals experimentally. How and why there should be this increased tolerance in syphilis cannot be defined; it would appear, however, that *Spirochæta pallida* and its products detoxify mercury in some unknown manner.

The Jarisch-Herxheimer reaction is mentioned in connection with this subject of the etiology of toxic reactions by mercury for the sake of completeness and not because I believe it to be a direct toxic effect of the drug. As stated in Chapter LVIII, Jarisch, Kraus and Herxheimer described exacerbations of the cutaneous and mucous membrane lesions of the secondary stage of syphilis following the administration of mercury. We now know that a similar exacerbation may occur in the chancre and more particularly in the chronic lesions of the central nervous system, but less frequently than observed after the administration of arsphenamin and its substitutes. The commonly accepted theory is that mercury releases inflammatory substances by destroying spirochetes which increases the degree of vascular changes, cellular and serous exudation, but I have discussed this subject with detail in Chapter LVIII.

Fatalities Due to Mercury in the Treatment of Syphilis.—It is impossible to even estimate the fatal intoxications from mercury since introduced into Europe for the treatment of syphilis about 425 years ago. Doubtless, however, there was a high mortality in the first two hundred years, if one may judge from the accounts of the barbarous and reckless fashion with which the drug was administered and especially be inunction and fumigation. Gaspard Torella in 1497 wrote: "Avoid, like the plague, these murderous ointments of charlatons, who have already so many victims." Rabelais congratulated Gargantua on having relieved the sufferings "of the poor syphilitics, anointed to the point at which their teeth started like the keys of an organ when played on." Ulrich de Hutten relates a case in which three patients were suffocated to death in one of the fumigating "stoves."[35]

In 1913 Wolffstein[36] reviewed some 108 fatalities from mercury in the treatment of syphilis recorded in the literature since 1883. Of these deaths only one was the result of oral medication due to five pills of one grain (0.06 gm.) each of mercury; evidently this patient was hypersensitive. There was one death from inhalation and nineteen from inunctions. Seven resulted from injections of soluble salts and seventy-eight from insoluble salts, thirty-

one of the latter being due to gray oil (*oleum cinereum*). Ehrlich and Hata stated about twelve years ago that up to that time at least eighty deaths had been caused by injections of gray oil. Of course, these figures do not include all of the fatalities from mercury administered in the treatment of syphilis; doubtless an equal or even larger number have never been recorded at all although the mortality at present per incidence of cases is undoubtedly smaller than reported for arsphenamin since its introduction for the treatment of syphilis fourteen years ago.

Prophylaxis of Toxic Reactions from Mercury in the Treatment of Syphilis.—This naturally brings us to a more complete discussion of the prophylaxis of toxic reactions when mercury is administered for the treatment of disease and especially of syphilis. Ordinarily this consists of reducing excessive smoking and an inspection of the gums and teeth with appropriate preliminary treatment to reduce the chances of ptyalism, siderosis, gingivitis and stomatitis; the correction of gross dietetic errors and constipation to reduce the chances of gastro-intestinal disturbances of diarrhea, colic, malaise and loss of appetite and finally a careful examination of the urine for albumin and casts, as indicative of the condition of the kidneys, especially if previous treatment with mercury, bismuth and arsphenamin or its substitutes had been given. In exceptional cases renal functional tests may be required, but liver functional tests are seldom required as is sometimes the case when the organic arsenicals are being administered.

But in addition to these primary considerations other factors are worthy of consideration and especially the kind of compound employed and the route of administration; both bear an important relation to the prevention of various toxic reactions by mercury.

Prevention of Ptyalism, Gingivitis and Stomatitis.—Of most importance is the condition of the mouth. If this is found healthy, treatment may be started at once, but otherwise the patient should be referred to a dentist for the extraction of stumps, the filling of cavities, removal of tartar and treatment of gingivitis if present; excessive smoking should be forbidden. During treatment with mercury the mouth should be inspected at frequent intervals and the patient requested to brush the teeth and gums night and morning with a good dentrifice. Patients should always be informed that they are taking mercury and is well to educate them with regard to the buccal accidents so that they may discontinue treatment upon the first appearance of ptyalism, halitosis, bad taste or soreness of the gums. Mercurial treatment should be always suspended on the least sign of buccal irritation and not resumed until all symptoms have disappeared. With these precautions salivation is quite uncommon and indeed, rare, when the patient cooperates with the physician. In hypersensitive individuals, however, salivation and even stomatitis may develop without warning and especially when intramuscular injections of large doses of insoluble salts (gray oil) especially are given.

Fournier states that in therapeutic doses protiodid of mercury causes more salivation than mercuric chlorid; I believe this is true, whereas, Hutchinson's old favorite mercury with chalk is well borne. Inunction is more likely to produce buccal accidents than ingestion, characterized by sudden onset, intensity and diffuseness of the stomatitis. Intramuscular injections of the insoluble salts, and especially of gray oil, are particularly dangerous because of slow absorption and accumulative action. Therefore, when it is necessary to give mercury to cases with "bad mouths," great case is required in the choice of compound and route of administration. My favorite start is with 1 grain of mercury and chalk three times a day and, if well borne, inunctions

of calomel or blue mass are given later. Injections are not given at all unless absolutely required in which case preference is given small doses of salicylate in almond oil because this salt is more soluble in the body juices and less likely to give an "explosive" stomatitis than calomel or gray oil.

Prevention of Gastro-intestinal and Nutritive Disturbances.—Some patients cannot take mercury in any form on account of gastric and intestinal disturbances as loss of appetite, pain and diarrhea. Administration by mouth may be particularly disagreeable in these respects and for this reason opium is sometimes incorporated. Mercury with chalk, however, is sometimes tolerated when protiodid and bichlorid cannot be given. Inunctions are much less likely to produce these symptoms; likewise intramuscular and intravenous injections. Constipation should always be corrected; also errors in diet and excessive drinking of alcoholic beverages.

Of great importance in this connection, as emphasized by both Fournier and Hutchinson, is intermittent treatment in order to give the organs of absorption and elimination a rest and avoid over accumulation of mercury.

Sometimes patients are better able to withstand mercury when it is administered by inunction along with hot baths and the drinking of sulphur waters. Fournier was confident that this was the case with patients treated by Doyen at Uriage and it doubtless constitutes an important part of the success of the inunction treatment of syphilis at Aachen and the Hot Springs of Arkansas at the present time. It is highly probably that the sulphur is absorbed in sufficient amounts to detoxify mercury or in some manner minimize its injurious cellular effects.

Prevention of Renal and Hepatic Disturbances.—The condition of the kidneys is always a matter of paramount importance during the administration of mercury and upon the first appearance of albumin, casts and erythrocytes in the urine, not otherwise accounted for, administration should cease until the evidences of renal irritation have disappeared. Ingestion is least likely to produce nephritis, but my impression is that this route is generally contraindicated in the presence of hepatic disorders probably because of direct absorption in the portal circulation. As a general rule, mercury should not be given at all in the presence of evidences of nephritis or recent recovery therefrom, but if it must be administered preference should be given small intramuscular doses of the salicylate in almond oil every ten days, because a portion of this is absorbed and eliminated before dissociation; or, intravenous injections of flumerin may be given, which is less likely to produce renal irritation than the bichlorid, succinimid or cyanid of mercury, probably for the same reason.

Prevention of Local Reactions.—When intravenous injections are given phlebitis and sclerosis of the veins and thrombosis may be avoided by using dilute solutions and injecting with a small (No. 22) needle. It is also well to use three or four veins or locations in rotation, which is not a difficult matter with most patients, even on the same arm.

Pain and tenderness from injections can be controlled to some extent by giving the injections epifascially (intermuscularly) rather than intramuscularly, as described in Chapter LX. By incorporating an anesthetic, as 0.1 c.c. of 2-per cent. butyn in each injection, the immediate pain is prevented. But the anesthetic does not control the late pain and tenderness sometimes requiring patients "to eat off the mantel" for a few days. These, however, are frequently caused by injecting too superficially or too near the sciatic nerve. Injections of calomel are usually more painful than injections of the salicylate and gray oil; the salicylate in almond oil is probably the least painful. The soluble salts and particularly bichlorid frequently produce

considerable pain although much less when given in almond oil than when dissolved in water or saline solution.

Prevention of Acute Toxic Reactions from Intravenous Injections.—These cannot be always avoided and especially if large doses are given but the incidence and severity are greatly reduced by two factors, namely, dilution and slow injection. Flumerin for example, is generally given in a 2 per cent. solution, 15 c.c. carrying 3 grains for an average adult or 0.003 gm. per kilo; but I believe it is better to use a 1-per cent. solution and inject 30 c.c. very slowly with a No. 22 needle. Mercurosal, mercurophen and the succinimid may be injected intravenously usually without reactions in ordinary doses, but always slowly and well diluted. Colloidal calomel and colloidal mercury are also well borne, the former being widely employed in Germany in dose of ¼ gram (0.015 gm.) for an adult. Bichlorid, benzoate, cyanid and other soluble salts should not be injected because of their hemolyzing and precipitating effects.

Contraindications to the Administration of Mercury.—Hypersensitiveness constitutes the chief contra-indication to the administration of mercury in any form and by any route. Some individuals are so hypersensitive that even swabbing or gargling the throat with 1:2000 solutions of mercurophen or bichlorid may produce acute intoxication with scarlatiniform rashes; others are less hypersensitive but yet rendered perfectly miserable by even small doses regardless of the route of administration. It is well not to force mercury under such conditions and especially since we have other antisyphilitic remedies today which the older syphilologists did not possess. Fixed mercurial dermatoses also contra-indicate the administration of mercury because of exacerbations of the lesions.

Nephritis, and especially acute nephritis whether syphilitic or otherwise, is usually a contra-indication; severe gingivitis (pyorrhæa alveolaris), aphthous stomatitis and acute or chronic gastro-intestinal disorders are likewise contra-indications in most instances and especially since other remedies like neoarsphenamin are available. Pregnancy is not of itself a contra-indication.

Etiology, Symptoms and Treatment of Toxic Reactions Produced by Mercury in the Treatment of Syphilis. *Clinical Classification of the Toxic Reactions of Mercury.*—Despite the usual care and precautions in the administration of mercury in the treatment of disease, various toxic effects may be produced and especially when patients ignore advice and directions and neglect to properly coöperate with the physician. Furthermore, when the insoluble salts are administered by intramuscular injection, toxic effects may occur with great suddenness, due to delayed absorption followed by sudden absorption of excessive amounts.

The various lesions may be grouped from the clinical standpoint somewhat as follows:

Acute colloidal shock reaction	
Gastro-intestinal disorders	Salivation or ptyalism
	Siderosis and halitosis
	Gingivitis and stomatitis
	Gastritis and ileo-colitis
Renal disorders	Polyuria
	Albuminuria
	Nephritis
Cutaneous disorders	Simple erythematomacular rashes
	Pruritus
	Scarlatiniform erythema with desquamation
	Erythema multiforme
	Dermatitis exfoliativa
	Exacerbations of syphilitic rashes (Jarisch-Herxheimer reactions)

Disorders of the nervous system	Neuritis
	Neural Jarisch-Herxheimer reactions
	Neurorecurrences
Disorders of nutrition	Chloro-anemia
	Anorexia, fatigue and emaciation
	Caries of bone
Accidents of injection	Phlebitis and thrombosis
	Pain, nodosities and sloughing
	Pulmonary embolism

Acute Colloidal Shock Reaction from Intravenous Injections of Mercury.—Various soluble salts of mercury are administered by intravenous injection in the treatment of syphilis and especially the succinimid, benzoate, cyanid and more recently, flumerin, mercurophen and mercurosal; mercurochrome is sometimes administered by this route for the treatment of bacterial injections, as already described and discussed in Chapter VIII.

In the doses ordinarily given for the treatment of syphilis, acute reactions are but rarely encountered. When mercurochrome is administered in a dose of approximately 0.005 gm. per kilo in the treatment of local and general bacterial injections, an acute reaction of fever, chilliness, leukocytosis and diarrhea may develop within an hour or two which may be due to acute colloidal shock analogous to the shock following intravenous injections of colloidal preparations of the heavy metals in general; doubtless, similar reactions would follow the injection of other salts of mercury if the doses were proportionately as large as that of mercurochrome which is given in about one-half to one-third of its maximum tolerated dose, whereas in the treatment of syphilis the dose of the other compounds just mentioned, is usually one-sixth to one-twelfth or less of their maximum tolerated doses as stated on page 740.

White, Hall, Moore and Young[37] state that intravenous injections of flumerin in dose of 0.003 to 0.005 gm. per kilo is only exceptionally followed by slight nausea, but sometimes by severe retching and vomiting tending to subside spontaneously within half an hour. They suggest that these effects may be central in origin and that dosage, number of injections given, concentration of solution, and rapidity of injection apparently exert no influence in their production. Cole, Driver and Hutton[38] state that intravenous injections of mercurosal in dose of 0.2 gm. sometimes produced "weakness" for the following twenty-four hours, but no other ill effects. Stokes has employed intravenous injections of the succinimid in dose of ¼ grain (0.015 gm.) without ill effects and I have administered mercurophen intravenously in dose of ⅓ grain (0.02 gm.) during the past three years without reactions. Monges and Raybaud[38a] record a case of fatal edema of the lungs following intravenous injections of mercury cyanid.

It would appear, therefore, that when mercurials are injected intravenously in doses not larger than one-sixth of their maximum tolerated doses, that acute reactions occur in but a small percentage of cases; when the dose is one-twelfth or less than the maximum tolerated dose acute reactions are practically unknown. This is especially true of pseudo- and half-complex compounds which do not dissociate and ionize rapidly. The late effects, however, as salivation, stomatitis, colic and nephritis may follow intravenous injections.

The *treatment* of acute colloidal shock reactions is purely symptomatic and along the same lines described for the treatment of the acute physico-hemoclastic reaction sometimes produced by arsphenamin (page 674).

Mercurial Salivation (Ptyalism).—An increased flow of saliva sometimes associated with a metallic taste is one of the earliest signs of mercurialism.

This may not be accompanied by any evidences of inflammatory changes in the gums or buccal mucosa and has been ascribed to the action of mercury upon the sympathetic nerves of the salivary glands along with direct irritation of these tissues by the excretion of mercury. In some cases, however, mercury has not been found in the saliva, the effects being ascribed purely to stimulation of the vasomotor nerves with extreme dilatation of the vessels, and may occur within a matter of ten or fifteen minutes after administration.

The tendency to salivation varies greatly among different individuals probably because of variations in susceptibility to vasomotor and autonomic disturbances. No compound of mercury is entirely free of these effects although they vary greatly in this respect. Inunctions and massive intramuscular injections are especially likely to produce the disorder. Salivation always accompanies mercurial gingivitis and stomatitis; when it occurs alone, due care must be exercised of course in diagnosis if the iodids are being taken at the same time since the latter, and not the mercury, may be responsible.

Treatment for salivation alone is not required beyond stopping medication. Local mouth washes may give some relief but do not materially influence the salivary glands.

Mercurial Siderosis and Halitosis.—The "blue line" of the gums (siderosis) and foul breath (halitosis) are well-known signs of mercurialism. Both, and especially the former, may develop insiduously without evidences of sufficient salivation to attract attention. Halitosis is especially likely to accompany severe stomatitis.

The "blue line" first develops in the free margin of the gums of the lower jaw about the central and lateral incisors and is easily detected by inspection. Infected gums (pyrorrhæa alveolaris) are especially likely to develop siderosis. According to most investigators the "blue line" is due to deposits of mercury sulphid in the endothelial cells of the capillaries followed by deposits in the connective tissues of the gums. Mercury is excreted by these channels and is believed to be converted into the insoluble and irritating sulphid by hydrogen sulphid in the tissues produced by bacteria; hence, in dirty mouths and cases of bacterial gingivitis, the "blue line" is especially prone to appear because hydrogen sulphid is particularly apt to be present.

Halitosis or "bad breath" is not due merely to the presence of mercury in the saliva since the metal is odorless; it is due rather, to putrefactive changes brought about by bacteria and yeasts in the gums, caries teeth, tonsils and saliva; sometimes it is due to gastro-intestinal disorders rather than to local conditions in the mouth.

There is no *treatement* for siderosis aside from cessation of mercurial medication. It is not always necessary, however, to interrupt a short course of treatment when it appears although the dose should be reduced. There is ordinarily little danger of gingivitis and stomatitis if the gums are otherwise sound and healthy and the patient duly careful in the cleansing of the mouth and gums twice daily. It gradually disappears although the time required dpends upon the amount of mercury to be eliminated and the degree of bacterial activity in the gums. Careful hygiene of the mouth before and during mercurial medication are of great importance in the prevention of these accidents. The *treatment* of halitosis requires a careful clean up to the mouth, correction of dietary disorders and gastro-intestinal disturbances including constipation if present and the frequent use of a mouth wash of which my favorite is a mixture of a solution of potassium chlorate and *liquor antisepticus* properly diluted.

Mercurial Gingivitis and Stomatitis.—Localized or diffuse inflammation of the gums (gingivitis) usually follows the "blue line," but may develop

suddenly and without warning; local or diffuse inflammation of the buccal mucosa (stomatitis) and of the tongue (glossitis) usually follow the gum lesions, but sometimes, and especially when large amounts of mercury are suddenly absorbed, develop without warning.

These inflammatory changes are ascribed to excessive irritation of the tissues by the excessive excretion of mercury along with vasomotor changes produced by the metal; Besseren[39] has recently reviewed the literature in a thorough manner and subscribes to the view that the changes are due to local effects superimposed on more general or widespread vascular and other changes which made possible the local lesions.

As a general rule gingivitis and stomatitis follow siderosis of the gums and cheek because the deposits of mercury sulphid produce necrosis of the tissues and thereby open up avenues of bacterial infection. The gums are tender, soft, red, bleed easily and recede from the roots of the loosened teeth which become grayish black and tend to caries. The buccal mucosa becomes swollen and tender with grayish-yellow ulcers due to contact with the teeth and especially the molars of the lower jaw. The tongue becomes swollen, flabby and indented with impress of the teeth; irregular, broad and shallow ulcers appear on the edges. The fauces may become red and swollen causing dysphagia, dribbling of saliva and fetid breath.

With careful hygiene of the mouth and careful dosage, stomatitis is uncommon. Fournier stated that he did not see more than one case in fifty with the methods practiced by him. Women are more likely to be affected than men. Intravenous injections of mercurosal in doses of 0.05 to 0.1 gm. every three to five days have rarely produced salivation and stomatitis because these doses are at least fifteen times smaller than the maximum tolerated dose; flumerin, on the other hand, has produced salivation and stomatitis in about 30 to 36 per cent. of cases, because the doses (0.003 to 0.005 gm. per kilo) are so large, these amounts being about one-sixth to one-tenth of the maximum tolerated doses. I have never observed salivation or stomatitis following a series of intravenous injections of mercurophen in dose of ⅓ grain (0.02 gm.) to adults, because this amount is at least twenty times below the maximum tolerated dose.

In other words salivation, gingivitis and stomatitis bear a relation to the degree of dissociation and ionization of mercury before elimination occurs and this in turn is influenced by the kind of compounds administered and the size of the dose.

In the *treatment* of gingivitis and stomatitis mercurial medication should be stopped, smoking stopped or greatly reduced, and the gums and mouth frequently cleansed with diluted *liquor antisepticus* or with a mixture of this solution and one of potassium chlorate. As a general rule, these measures are sufficient as the lesions tend to disappear rather promptly when the mercury is stopped unless injections of the insoluble salts have been given when they may continue for an indefinite time depending upon absorption. Dennie states that intravenous injections of sodium thiosulphate are helpful and these may be tried in severe cases after the plan described on page 695 for the treatment of arsenical dermatitis. I have also employed mouth washes of 10-per cent. solutions of sodium thiosulphate, after each meal and at bed time, followed by diluted *liquor antisepticus*, apparently with some good effects. In severe cases the diet should be bland and of necessity usually liquid, because of the pain attending efforts to masticate food. The free use of alkaline waters is helpful.

Mercurial Gastro-enteritis.—When mercury is swallowed accidentally or with suicidal intent, mercuric chlorid being usually taken, a very acute and

almost immediate gastritis with vomiting may occur, due largely to local irritation of the gastric mucosa. When mercury is administered in the treatment of syphilis, and especially the protiodid and bichlorid, colic and diarrhea sometimes develop. Mercury administered by inunction, inhalation or injection, however, may produce exactly the same symptoms.

These effects may be due, therefore, to direct local irritation when mercury is administered by ingestion or to the effects of mercury during elimination by the bile and intestinal mucosa after any method of administration. The mechanism is apparently exactly similar to the production of gingivitis and stomatitis in that the mercury produces vascular changes of congestion and hemorrhage along with direct irritation of the vascular endothelium and tissues of the mucosa during elimination. Siderosis occurs as in the mouth, due to deposits of mercury sulphid from the hydrogen sulphid of the intestinal bacteria; this in turn may be followed by ulceration and especially of the mucosa of the colon, although ulcers may be produced without deposits of mercury sulphid.

Some individuals are absolutely unable to take even fractions of the usual doses of mercury by any route on account of gastro-intestinal disturbances. As a general rule, diarrhea is the first development, occurring in a few hours or after a few days following administration. Nausea, vomiting, vertigo, thirst and colic with gaseous distention may precede or accompany the diarrhea. The stools are watery, fetid and accompanied by tenesmus; later blood, pus and even shreds of intestinal mucosa may be present.

The frequency of gastro-intestinal reactions varies greatly with different individuals, the compound used and the method of administration. Oral administration is more likely to produce them than inunctions or injections; mercury with chalk is oftentimes well borne when the protiodid and bichlorid cannot be given. Intravenous injections of flumerin at two-day intervals produces about 4.3-per cent. reactions of immediate nausea and vomiting but less than 1 per cent. of diarrhea and cramps. As in gingivitis and stomatitis, these ill effects vary with the compound in relation to the rapidity of its dissociation and ionization and the amount of mercury contained.

In *treatment* the first step is to stop mercurial medication. The diet should be bland and largely of milk. Cathartics are not required because peristalsis and intestinal cramps or contractions are severe enough. Bismuth subgallate with opium should be given until relief is obtained. Alkaline drinks are helpful as one teaspoonful of potassium tartrate and one-half teaspoonful of sodium citrate in a glass of water, orangeade or lemonade.

Renal Disorders Due to Mercury.—Since mercury is largely eliminated by the kidneys it is not surprising that these may be involved early in acute and chronic mercurialism. In acute bichlorid poisoning, the nephritis with anuria and uremia constitutes the most dangerous lesions, but during the treatment of syphilis signs of renal irritation and nephritis must be looked for routinely and especially if intravenous injections are being given.

The first sign is polyuria due to the increased vascular engorgement of the organs as a result of the influence of mercury upon the vasomotor system. Glycosuria may appear as a result of sympathetic stimulation, hepatic disturbances or increased permeability of the renal cells. Polyuria and glycosuria, however, are not usually detected during the treatment of syphilis since the onset of renal irritation is so mild and gradual. As a general rule albuminuria is the first sign of renal disturbance accompanied by casts and, in severe cases, by blood and much tubular epithelium. Anuria may now develop and constitute the great and chief danger of acute mercurial poisoning.

The histological changes have been already described. Opinions vary, however, on the mechanism of production of these changes. Most investigators of this subject believe that the changes are essentially the result of direct irritation of the glomeruli and tubules by mercury, the peculiar distribution of the lesions being due to distribution of the blood supply and drainage of these organs. Others, and especially MacNider, believe that the renal changes are largely due to acid intoxication and especially in acute mercurial intoxication with severe gastro-enteritis. In my opinion, the renal changes sometimes developing in the treatment of syphilis, like albuminuria with casts and decreased phenolsulphonphthalein return, are due to vascular engorgement of the glomeruli as a result of the influence of mercury upon vasomotor nerves and to cloudy swelling and necrosis of the glomerular and tubular epithelium, especially of the collecting tubules, by mercury in excessive amounts in the blood brought to these organs for elimination. Doubtless acid intoxication may be an added factor in the production of cloudy swelling and necrosis, but only in acute poisoning, like bichlorid poisoning, with severe gastro-enteritis. Bessesen and some other investigators believe that mercury probably forms a compound with the blood, as indicated by a decreased blood count and hyperemia of bone-marrow, with a reduction of oxygen and an increase of lactic acid, which, together with the mercury, act on the sympathetic system as irritants in addition to the formation of albuminates of mercury in the cells of the kidney rendering them less active.

The frequency of renal changes during the mercurial treatment of syphilis varies greatly according to the nature of the compound administered, as influencing the rate of dissociation and ionization of the mercury, the route of administration and the content of mercury. When treated by ingestion, renal irritation is very uncommon, as shown by the experience of Fournier and Hutchinson, the two great exponents of this route of adminstration.

Inunctions produce more irritation, as likewise intramuscular injections, and especially intravenous injections of the soluble salts. It is always advisable to examine the urine for albumin and casts at least once a week or fortnightly during active mercurial medication. Flumerin is reported by White and his associates as producing transient albuminuria in about 22 per cent. of cases with decreased phenolsulphonphthalein return in about 5 per cent., when the usual doses of 3 to 5 gm. per kilo are injected intravenously at two day intervals; mercurosal, mercurophen and succinimid apparently do not produce as much irritation largely because the doses are comparatively much smaller.

The *treatment* of mercurial nephritis developing in the course of mercurial medication in syphilis does not usually require anything more than stopping the drug. As a general rule, the albuminuria gradually disappears, although this depends upon the amount requiring elimination. In acute mercurial nephritis, however, more energetic measures are required and especially in bichlorid poisoning. A large number of methods have been described. Weiss has reported unusually good results from the intravenous injection of 1000 to 1500 c.c. of Fischer's solution, prepared by dissolving 10 gm. of crystallized sodium carbonate and 15 gm. of sodium chlorid in 1000 c.c. of distilled water followed by sterilization or, of a sterilized 4-per cent. solution of sodium bicarbonate in water. In severe poisoning the infusion may be required a second or third time on successive days, the object being to correct the acid intoxication and render the urine alkaline to methyl red and to keep it so; 8 ounces of "imperial drink" are given internally six to eight times a day (1 teaspoonful of potassium bitartrate and ½ teaspoonful of sodium citrate in 8 ounces

of water, orangeade or lemonade). In addition to this alkaline treatment it may be serviceable to administer daily intravenous injections of sodium thiosulphate in doses of 1 gram in 10 c.c. of sterile distilled water.

Mercurial Dermatoses.—It is now well known that mercury may produce a variety of skin lesions somewhat resembling those produced by arsphenamin and its substitutes, but much less frequently and usually of much less severity. Almkrist[40] lately studied thirty-eight cases and classified them as simple and complicated or infective. He found that intramuscular injections of mercury salicylate was responsible for most of them, gray oil less and mercurial ointment the least.

Mercurial dermatitis may be caused by inunctions, and may be localized to the sites of application, or more generalized. Fournier states: "This dermatitis may take the form of an *erythema*, which may be diffuse or in confluent patches, extending over the whole region of inunction. This disappears in a few days, and is followed by slight desquammation. In other cases there is *mercurial eczema*, which consists in a deep red diffuse area of erythema covered with confluent vesicles, full of clear fluid at first, afterwards turbid. This is accompanied by inflammatory swelling of the skin, local heat, and intense pruritus. This generally lasts only a short time, and is followed by slight desquammation. In some cases, however, instead of a circumscribed dermatitis, a generalized eruption is produced, starting from the seat of inunction and spreading over nearly the whole skin. This is erythematous in some places and ezematous in others, and degenerates partially into an *exfoliating dermatitis*, which may last for weeks. It is sometimes accompanied by severe general symptoms, and has been described under the name of *hydrargyria febrilis maligna*. But this danger is not peculiar to the inunction method, and may occur with all the different modes of mercurial administration. Moreover, it is due to a rare idiosyncrasy."

Mercurial dermatitis most commonly occurs after the first dose of the drug, but sometimes it does not appear for several days or after several weeks. Fournier states that it is a curious fact that these eruptions are not, as a rule, accompanied by other signs of mercurial intolerance, such as diarrhea, stomatitis, etc.

Mercurial dermatitis may appear as a *simple erythema, a scarlatiniform erythema*, as an *urticaria*, an *erythema multiforme*, or, more rarely as a severe *dermatitis exfoliativa*. In other words, the lesions may be quite similar to the better known arsphenamin rashes, but usually of a milder character; indeed, as recently stated by Wright[40a] mercury may produce almost as many cutaneous reactions as arsphenamin, and it is well to bear this in mind when a patient receiving mixed treatment develops an eruption, for it may be due to either drug or to the combination.

Complicated mercurial dermatitis, as classified by Almkrist, is characterized by an irregular and very long course, often with alternate improvements and exacerbations. When the lesions become secondarily infected with bacteria, he classifies the exanthem as infected mercurial dermatitis. In the rare very acute cases of exfoliating mercurial dermatitis there may be exfoliative ileo-colitis, bronchitis, vaginitis or exfoliating conjunctivitis as in arsenical exfoliative dermatitis.

Fixed exanthema in which the outbreak is localized and recurring after each administration of mercury at the same site, may occur as described by Langer[41] Hubschmann[42] and others.

It is hardly necessary to caution against a diagnosis of mercurial dermatitis in cases of secondary syphilis showing exacerbations of skin and mucous membrane lesions after the first large dose or two of mercury; these are the

original Jarisch-Herxheimer reactions due to the influence of the drug on spirochetes and not primarily toxic mercurial exanthems. Since arsphenamin and its substitutes are now usually employed in the treatment of acute syphilis, they are not as frequently seen as ten years ago.

Fournier was of the opinion that idiosyncrasy to mercury was the primary *cause* of these exanthems. Almkrist assumes that the toxic action of mercury produces a vascular dilatation with edema by paralysis of the vasomotor nerves, followed by a proliferation of epithelium and secondary bacterial infection. It would appear, therefore, that the cause of mercurial dermatitis is exactly similar to the explanation which I have offered for arsenical dermatitis, namely, that there is a natural or acquired allergic hypersensitiveness to the metal which is expressed in the form of disturbances of the vasomotor nerves resulting in vasodilation and serous exudation which thereby intensifies the physiological vasoparetic effects of mercury. Whether or not allergic sensitiveness to bacteria from focal infections plays a part by way of the mercury stimulating or disturbing such foci with the result that an explosive allergic reaction occurs, as claimed by Stokes, Keidel and Moore in the mechanism of arsphenamin dermatitis, cannot be stated, but I do not believe that such occurs because the mercurial exanthems are so frequently engendered by doses of mercury so small that it is not reasonable to assume that they are capable of disturbing foci of bacterial infection, as at the roots of the teeth, in the tonsils or in the accessory sinuses.

The *treatment* of mercurial dermatitis is exactly the same as described for the treatment of arsenical dermatitis on page 693. In mild cases nothing is ordinarily required but withdrawal of the drug and the application of soothing lotions. In severe cases the diet must be restricted and sodium thiosulphate may be administered by intravenous injection as advised by Dennie[43] Hoffman and Scheus.[44] It is well not to resume the administration of mercury after recovery, but to continue the treatment of syphilis with the arsenicals or bismuth.

Mercurial Neuritis, Neurorecurrences and Neural Jarisch-Herxheimer Reactions.—Mercury does not involve the peripheral nerves with anything near the frequency of arsphenamin and its substitutes. Indeed, mercurial neuritis is rare in the treatment of syphilis although cases have occurred in acute mercurial poisoning as recently reviewed by Beeson.[45] Paresthesia, polyneuritis, toxic amblyopia, etc., so frequently encountered when the organic arsenicals are being administered, are almost unknown in mercurial medication. When intramuscular injections are given, nerves may be involved with referred pain to the leg and foot and even temporary paralysis of one or more muscle groups may occur.

Neural Herxheimer reactions, that is, exacerbations of lesions of the central nervous system and especially of the optic, oculo-motor and auditory nerves after the first few doses of mercury, are very exceptional occurrences and, indeed, it is a good practice to start the treatment of chronic syphilis likely to develop these lesions with a course of mercury in order to avoid them before arsphenamin or one of its substitutes is given.

Neurorecurrences, however, or the exacerbation of neural lesions upon the cessation of treatment, may occur just as in arsphenamin treatment when the restraint upon spirochetic activity is removed.

Effects of Mercury upon the Blood and General Nutrition.—When mercury is taken in toxic doses it is apparently followed by a destruction of erythrocytes producing a chloro-anemia and leukocytosis; the literature has been recently reviewed by Bessesen.[46] But otherwise mercury is to be regarded as stimulating the bone-marrow, with an increase of erythrocytes and hemo-

globin. It is very well known clinically as influencing favorably the various syphilitic anemias, although not as rapidly as arsphenamin and its substitutes.

In the treatment of syphilis when the administration of mercury is greatly prolonged or persisted in with patients who do not bear it well, there may occur languor, anemia, anorexia, fatigue and emaciation, but almost exclusively under the two following conditions: (1) when given in large doses causing gastro-intestinal disturbances; (2) when given too long, even in moderate doses. Otherwise the administration of mercury quite commonly results in an increase of weight, correction of anemia and a general improvement in health and nutrition, not so much because of the drug possesses "tonic" properties, as because of destruction of *Sp. pallida* and its products.

The bone changes of absorption and caries are likewise only observed in chronic severe poisonings; they were not uncommon in the fifteenth and sixteenth centuries as a result of barbarous methods in administration, but are very rare at the present time although caries and discoloration of the teeth and absorption of the alveolar processes are sometimes seen in severe cases of mercurial gingivitis.

Mercurial Phlebitis and Thrombosis.—When mercury is administered by intravenous injection, phlebitis may occur but not as frequently as in the administration of arsphenamin. Flumerin is said to be non-irritating to the veins even after many injections, although moderately painful swellings, lasting about twenty-four hours, have resulted from accidental perivascular injections. Cole and his associates have noted sclerosis and thrombosis in a few instances after the administration of mercurosal; mercurophen is also irritating unless well diluted—1/3 grain (0.02 gm.) in 20 c.c. of water being without irritation. The succinimid is much less irritating than the bichlorid and cyanid of mercury.

If treatment is required, it may be the same as described on page 710 for accidental arsphenamin phlebitis and peri-phlebitis. As a rule, the local application of wet dressings of a saturated solution of magnesium sulphate for a day or two is all that is required.

Pain, Nodosities and Abscesses from Intramuscular Injections of Mercury.—Intramuscular injections of mercury almost always produce some pain, although the degree varies greatly in different individuals. By incorporating an anesthetic, as 0.1 c.c. (2 or 3 drops) of a 2-per cent. solution of butyn, the immediate pain is prevented, but not the late pain coming on after a day or two. In a general way, the pain produced by mercury is greater than that produced by bismuth; this is certainly true of the insoluble salts of both metals.

As a rule, the pain from intramuscular injections of the soluble salts of mercury comes on in an hour or two or several days after injection; in the latter cases it is more acute and continuous with tenderness of the whole region. In my experience, the bichlorid and biniodid of mercury have produced more pain than mercurosal; mercurophen produces so much pain that it cannot be administered at all by intramuscular injection. Flumerin has not been employed by this route of administration.

Intramuscular injections of the insoluble salts of mercury also produce pain and especially injections of calomel. Gray oil is possibly a little less painful and the salicylate is much less irritating. The degree of pain and complaint varies, however, with different patients, but in the majority, a series of calomel injections in dose of 0.05 gm. (about 1 grain) cannot be given, whereas it is usually possible to give a series of injections of the salicylate in the same dose. In rare instances fever and such symptoms as malaise, ano-

rexia, headache, insomnia, and weakness accompany the local reaction and confine the patient to bed for several days.

As a general rule, very little can be done in the way of treatment. Hot or cold applications of saturated solutions of magnesium sulphate in water may be tried if the patient is confined to bed. Otherwise mild counter-irritation by occasional applications of diluted tincture of iodin may afford relief.

The nodosities from injections of the soluble salts usually vary in size from a filbert to a walnut. They are rounded, rather diffuse, hard, and sensitive to pressure. They often disappear in a few days, but sometimes persist for weeks. Sometimes they give rise to a hyperesthetic state of the whole region in which they are situated, especially when they are multiple. After injections of calomel they may persist for weeks and months and occur in about two thirds of the cases. Gray oil nodosities are also likely to persist for long periods of time; the salicylate is less likely to produce them although they occur and often persist with some tenderness for weeks and months; in the subcutaneous tissues I have known them to persist for several years due to fibrous tissue encapsulation.

Nodosities may be treated by occasionally painting the skin with tincture of iodin for counter-irritation and gentle massage and pinching to encourage complete absorption of the mercury, inflammatory exudate and fibrous tissue. Sometimes, and especially when located in the subcutaneous tissue, they may be removed surgically.

Sloughing rarely follows injections of mercury as may occur after injections of arsphenamin. When mercury is given subcutaneously, however, large sloughs may develop and especially if secondary bacterial infection occurs. Abscesses are likewise rare; in Fournier's experience they occurred only in 19 injections in a series of 1410 injections of calomel. They are not usually caused by bacterial infection but are sterile abscesses due to chemical liquefaction necrosis by the mercury with dark chocolate colored fluid contents. They must be treated by incision and evacuation under aseptic precautions to prevent secondary injection.

Hemorrhages from accidental rupture of large blood-vessels in intramuscular injections are relatively rare; not infrequently, however, small superficial veins are punctured during the passage of the needle but without anything more than slight bleeding easily checked by pressure.

Pulmonary Embolism from Intramuscular Injections.—As previously stated, colloidal suspensions of calomel and of the metal mercury itself may be injected intravenously without danger of embolism if the particles are not much larger than erythrocytes as determined by microscopical examination. But when oily suspensions of calomel, salicylate or gray oil are accidentally injected and especially rapidly injected into a vein during the course of intramuscular injections, oil embolism of the lungs may result. Immediately, or a short time after injection, there is sudden dyspnea, rapid respirations, spasmodic cough, pain in the thorax, and even syncope; then on the next or following days, slightly blood stained expectoration, and the signs of localized patches of congestion and exudation. Recovery is the rule under simple treatment of rest in bed with sedatives.

CHAPTER LIV

PHARMACOLOGY OF BISMUTH IN RELATION TO METHODS OF ADMINISTRATION AND THE TREATMENT OF SYPHILIS

Since compounds of bismuth have been employed in the treatment of syphilis only during the past year or two, our knowledge of their pharmacology is quite incomplete and especially in relation to administration by intramuscular injection. It is true that for many years various salts of bismuth have been employed in the treatment of gastro-intestinal diseases by oral administration, in the form of dusting powders and Beck's paste, for surgical purposes and for aiding the preparation of roentgenograms; but

otherwise the therapeutic use of bismuth has been quite limited although the toxicological effects have been carefully studied and especially in relation to the use of these compounds in surgical treatment.

Much that has been stated on the absorption and elimination of mercury in Chapter LII is applicable to bismuth compounds, although the latter are much less volatile and are absorbed much more slowly from the gastro-intestinal tract. While Klauder[1] has employed daily inunctions of 0.5 to 2.0 gm. of bismuth trioxid in the treatment of syphilitic patients presenting cutaneous lesions, only feeble curative effects were observed, probably largely due to the fact that bismuth is less volatile than mercury which reduces the amount absorbed by inhalation of vapors or the swallowing of condensed vapors in the saliva. Absorption from the gastro-intestinal canal is likewise so slow and uncertain that this route of administration is not employed in the treatment of syphilis; intravenous injections of soluble salts, like potassium and sodium tartrobismuthate, have proven somewhat too toxic and dangerous, although bismuth hydroxid in colloidal suspension has been widely employed abroad in dose of 0.010 gm. (about $\frac{1}{6}$th grain) by intravenous administration. At the present time the intramuscular injections of potassium tartrobismuthate, sodium and potassium tartrobismuthate, bismuth oxid or other compounds suspended in vegetable oils are mostly employed, and I will therefore discuss the absorption and elimination of bismuth principally from the standpoint of this route of administration.

Absorption of Bismuth with Special Reference to Intramuscular Injection.—As stated in Chapter XXV, a large number of soluble and insoluble bismuth compounds have been tried in the treatment of experimental syphilis of the rabbit, including the precipitated metal and bismuth hydroxid in suspension, bismuth ammonium citrate, lactate, subgallate, oxyiodgallate quininbismuth iodid, trioxybismuthobenzoate and bismuth trioxid, but potassium tartrobismuthate, sodium tartrobismuthate and a quartenary compound known as sodium and potassium tartrobismuthate have been found by Sazerac and Levaditi and others least toxic and especially suitable for intramuscular injection either in isotonic solution or in suspension in a vegetable oil.

Of course, when bismuth is injected intravenously, either in the form of solutions of the water soluble salts like the tartrobismuthate or the insoluble compounds as bismuth hydroxid in colloidal suspension, the question of absorption is settled, since the drug is placed at once in the blood stream.

Studies upon the rapidity of absorption of bismuth into the blood after intramuscular injections do not appear to have been made, but the results of experiments in the treatment of syphilis of the testicles of rabbits have shown me that solutions of sodium and potassium tartrobismuthate are rapidly absorbed and probably the rate is comparable to the absorption of such soluble salts of mercury. It is well known, for instance, that absorption of soluble salts from the intestines or ulcerated skin occurs so rapidly that bismuth may be found in the urine within 10 to 15 hours after administration.

Suspensions of sodium or potassium tartrobismuthate or other bismuth salts in oil are absorbed more slowly and especially when injected in paraffin oil. Levy-Bing, Belgodère and Auclair[2] have studied the rate of absorption by means of roentgenograms of 0.015 gm. doses of bismuth hydroxid, washed with alcohol, suspended in olive oil, sterilized and injected every 2 to 7 days, and found that absorption was ordinarily quite rapid but varying according to the site of injection, compression and massage, etc. Fritz[3] has studied the absorption of "bismoluol," a dipotassium-bismuth preparation, administered in olive and paraffin oils. In the former menstrum absorption was

usually complete in a week; but in the latter, absorption was very irregular and retarded, because paraffin oil remains unchanged in the tissues forming a protective coating over the medicament whereas the vegetable oil is saponified by the alkaline tissue juices and readily absorbed. Beinhauer and Jacob[3a] have injected six preparations of bismuth into the gluteal muscles followed by roentgenological examinations for absorption with the following general results: "neotrepol and bicreol were more widely diffused and more quickly absorbed than most preparations. Iodobismuthate of quinine was most quickly absorbed but iodidism resulted in several cases. Bismudol was readily absorbed and very well tolerated. Potassium-bismuth-tartrate and bismuth salicylate were slowly absorbed and we found that the cumulative action must be considered when using these preparations. When using the quickly absorbable preparations, the toxic effect must be borne in mind."

It would appear, therefore, that in the treatment of syphilis preference is to be given the soluble salts of bismuth administered by intramuscular injection in doses of 0.1 to 0.2 gm. in a menstrum of sterile vegetable oils, like almond or olive oils, in amounts of 1 or 2 c.c. Under these conditions cumulative effects are not likely to occur and absorption is ordinarily complete in 5 to 7 days. As I shall discuss with more detail in the next chapter some tissue necrosis occurs about the deposited drug in the muscles with well-marked leukocytic infiltrations, but nevertheless absorption is quite rapid. The insoluble compounds, however, like the precipitated metal, are absorbed more slowly and in a degree comparable to the absorption of calomel, but apparently faster than the absorption of gray oil as indicated by the studies of Levy-Bing and his associates referred to above.

Absorption may also occur after the oral administration of the subnitrate and subgallate; according to Dorner and Weingartner,[4] small amounts of these basic salts are dissolved in the acid gastric juice followed by absorption. As shown by Kocher and numerous other surgeons, absorption may also occur when bismuth powders are applied to wounds or in the form of Beck's paste; quite a series of poisonings have been recorded, although, in some of these at least, the effects have been caused by the absorption of nitrites from impure preparations of bismuth subnitrate.

Mechanism of the Absorption of Bismuth.—Little is known of the mechanism of the absorption of bismuth. It is commonly stated that albuminates are formed in the tissues, similar to the albuminates of mercury, by dissociation of bismuth ions, which are rendered soluble in the tissue fluids and absorbed. I have observed that solutions of potassum tartrobismuthate and sodium tartrobismuthate in saline solution form precipitates somewhat slowly with serum, which, like the abuminates of mercury, are insoluble in saline solution; but doubtless these abuminates are rendered sollube in the tissue fluids by chemical reactions followed by absorption in the same manner as the absorption of the albuminates of mercury.

Absorption of the metal itself and of its insoluble salts also occurs by phagocytosis, as shown by the studies of Meyer and Steinfield,[5] Schmelzer,[6] and Langhaus,[7] on absorption from the intestines and wounds; Mayer and Baehr[8] have also demonstrated bismuth in phagocytic cells by a microchemical method, and doubtless phagocytic absorption plays an important rôle in the absorption of both organic and inorganic compounds, the phagocytized particles later undergoing solution in the cells or in the tissue fluids.

Distribution of Bismuth after Absorption in Relation to the Treatment of Syphilis.—The small amount of data available from chemical studies of the internal organs following fatal intoxications with bismuth, indicate that wide distribution occurs, the results being quite similar to those observed in

investigations upon the distribution of mercury. Analyses of the organs of human subjects, succumbing to poisoning following the application of bismuth to wounds and its use in paste, have shown its presence in the buccal mucosa, salivary and cervical glands, liver, spleen, kidneys and the walls of the gastro-intestinal canal. Dalché and Villejean,[9] for example, administered the subnitrate to dogs by subcutaneous injection followed by chronic poisoning and analyses of the organs of one animal showed that the concentration was least in the liver, but, owing to its large size, this organ contained most of the drug and, as will be shortly discussed, is actively concerned in its elimination in the bile. Similar results were observed in a case of fatal poisoning following the injection of 3 ounces of a 25 per cent. chemically pure paste of bismuth reported by Mayer and Baehr.

Of considerable interest in relation to the treatment of neurosyphilis is whether or not bismuth is to be found in the tissues of the central nervous system and cerebrospinal fluid. Aubry,[10] employing a modification of Léger's method, states that he was able to detect bismuth in a dilution of 1:600,000 and that with this method bismuth was found by Démelin and himself in the cerebrospinal fluid of patients treated with intramuscular injections of 0.2 gm. of "trepol" which is sodium and potassium tartrobismuthate. Jeanselme, Delande and Tenis[10a] employing the same method, which they state can detect one part of bismuth in a million, tested the cerebrospinal fluids of 31 cases of syphilis following intravenous injections of bismuth but with negative results in all.

It is highly probable, therefore, that bismuth has much the same distribution as mercury and lead and is to be especially found in those organs mostly concerned in its elimination, as the liver, kidneys, salivary glands, gums and colon. Syphilitic lesions and especially chronic or tertiary lesions of the skin and mucous membranes, periosteum and bones, as well as of the central nervous system and other internal organs, are known to show therapeutic improvement under bismuth administration and especially some types of neurosyphilis refractory or resistant to mercury and the organic arsenical compounds; these therapeutic results indicate, therefore, a widespread distribution of bismuth.

Elimination and Retention of Bismuth in Relation to the Treatment of Syphilis.—After absorption some bismuth is apparently stored in the liver and other organs, but most is gradually eliminated in the urine and bile; elimination also occurs by the salivary glands, buccal mucosa and probably the entire gastro-intestinal tract and especially from the first portion of colon. According to Fournier and Guénot, traces are to be found in the sweat; probably none is eliminated through the lungs. Apparently small amounts are also eliminated in the milk of lactating women, the whole mechanism of elimination being apparently quite similar to that of mercury.

Elimination of Bismuth in the Urine.—Even when given by mouth some bismuth may be found in the urine; Mayer and Baehr mention that Kuttner found 0.023 gm. in the urine of a case of gastric ulcer six days after the oral administration of one ounce of bismuth carbonate. Levaditi[12] states that bismuth appears in the urine within eighteen to twenty hours after the intramuscular injection of sodium and potassium tartrobismuthate, and that it continued to be eliminated in the urine for twenty to twenty-five days after a course of treatment consisting of a total administration of 2.0 to 2.5 gm. of this substance. Steinfield and Meyer in 1886 noted its presence quite constantly in the urine after subcutaneous injections of bismuth oxid and in 1818 Orfila observed the same after the oral administration of the subnitrate. Sometimes the urine when voided is discolored or becomes so after standing, which in the latter instance is due, according to Démelin, to the formation of sulphids of bismuth by the bacteria present. It would appear, therefore, that the kidneys are the main enunctories of bismuth, as is true of mercury and lead, and for this reason due care must be exercised, as stated by Higgins,[13] in the administration of bismuth for any

purpose; and I believe that this should apply to the treatment of syphilis with intramuscular injections of the tartrobismuthates, although I have frequently injected potassium tartrobismuthate in dose of 0.1 gm. in 2 c.c. of sterile almond oil once a week for six to twelve weeks, when traces of albumin with casts resulting from mercurial treatment have gradually disappeared from the urine.

Elimination of Bismuth in the Feces.—Following subcutaneous injections of bismuth oxid, Steinfield and Meyer in 1886 found bismuth in the bile, and since then several investigators have shown that considerable amounts are eliminated by this route. Apparently the liver is an important storage depot for the drug and likewise an important organ of elimination. The presence of bismuth in the feces is largely due, therefore, to elimination in the bile, but in addition some bismuth is eliminated in the mouth which is swallowed, as well as probably along the entire gastro-intestinal tract. In poisoning, the colon shows the most marked changes with blackish areas of ulceration; Steinfield and Meyer have stated that these effects are due to the precipitation of bismuth brought to the mucosa for elimination in the lymphatic and vascular channels by the formation of bismuth sulphid from the hydrogen sulphid in the colon and that these precipitates produce embolism, stasis and necrosis. The same explanation has been offered for the blackish deposits in the gums. Under these circumstances ulcers may be produced as the result of the stasis and direct irritating effects of the sulphid and the black discoloration of the feces is believed to be due in part at least, to the presence of these sulphid compounds. Schmelzer, however, has questioned this view, because similar pathological changes may be produced apparently in the absence of hydrogen sulphid in the colon of some animals like the goose. It is possible that a portion of the black deposits in the feces are oxids of bismuth, although there is but little oxygen available in the colon for their production.

However, there cannot be any doubt that bismuth is actively eliminated by the liver in the bile and by at least some portions of the alimentary tract, and especially the buccal mucosa and colon. It is also possible that some is eliminated in the pancreatic juices as in the case of mercury. Probably a portion eliminated in the bile and saliva is re-absorbed lower down, as may occur in the case of mercury with a repetition of the cycle. When bismuth is administered by mouth, of course the largest portion may be passed in the feces unabsorbed. As a general rule the feces are black, due to the formation of sulphids and oxids, but in some cases of enteritis the bismuth may be passed almost unchanged. Whether this denotes an absence of hydrogen sulphid or a change in the bacterial flora cannot be stated.

Elimination of Bismuth in the Milk.—Of special interest in relation to the treatment of syphilis of nursing infants by administration of drugs to the mother, is the elimination of bismuth in the milk. According to Cabot,[14] Henry and Chevalier showed in 1839 that bismuth may be eliminated in the milk of goats and Schmelzer states that Lewald also found bismuth in the milk of women. It is highly probable, therefore, that bismuth administered to nursing women may be eliminated in small amounts, at least, in their milk, but I do not know at this writing of any clinical observations upon the influence exerted upon syphilitic infants during the intramuscular injections of the tartrobismuthates to the nursing syphilitic mothers.

Retention of Bismuth.—Undoubtedly bismuth tends to become stored in some of the internal organs and especially the liver. Very probably other organs, as the kidneys and gastro-intestinal mucosa, likewise store small amounts, as in the case of mercury. Just what may be the capacity for storage in the different organs cannot be stated; nor do we have any information regarding the balance or equilibrium between storage and elimination as worked out by Lomholt for mercury. Very probably, however, all that has been determined for mercury is applicable in a general manner to bismuth, although, owing to a lower toxicity of bismuth and especially the tartrobismuthates employed in the treatment of syphilis, it is likely that the liver, kidneys and other organs can store larger amounts without apparent injury than is the case with mercury; likewise, it is probable that the blood may carry more than it may of mercury.

Nothing is known of the therapeutic activity of stored bismuth in syphilis except to state that in all probability it possess some value since Kolle[14a] has shown that when bismuth was injected subcutaneously in the ears of rabbits, the drug prevented the development of testicular syphilitic lesions until the deposit was removed by amputation, following which lesions usually developed; in other words it would appear that local deposits of bismuth may at least prove spirochetostatic and the same is probably true of depots of mercury. As is probably true of mercury, some of the stored metal is doubtless being constantly re-absorbed and may exert some therapeutic effect before elimination occurs. For this reason, curative effects may continue for some time after the cessation of intramuscular injections of the tartrobismuthates in syphilis and, indeed, clinical experience indicates that this is the case.

Mechanism of Therapeutic Activity of Bismuth in Syphilis.—The subject of the mechanism of curative activity of bismuth in syphilis has been already

discussed in Chapter XXV. It is highly probable that this mechanism is essentially similar to the spirocheticidal activity of mercury and largely dependent upon the ease with which the bismuth ions become dissociated. Very probably the toxicity of bismuth for both the cells of the host (organotropism) and for *Spirochæta pallida* (parasitropism) depends upon the bismuth ions, as there is no evidence to show that new compounds are produced by processes of oxidation or reduction as in the case of the organic arsenical and antimonyl compounds; nor is there any evidence to show that bismuth increases the production of spirocheticidal antibodies by direct stimulation of the antibody producing tissues.

Just how much bismuth is required in the blood and tissue fluids to exert spirocheticidal effects is not known. As stated in Chapter XXVIII, I have found that 1:80 solutions of the tartrobismuthates in serum and tissue fluids are required to bring about the destruction of *Sp. pallida in vitro* in an exposure of 30 minutes at 37°C., but whether more or less than this concentation is required *in vivo* cannot be stated. The single minimal curative dose of the tartrobismuthates in acute testicular syphilis of rabbits is about 0.05 gm. per kilogram by intramuscular injection, and if all of this were absorbed before elimination occurred would probably yield a dilution in the blood of approximately 1:1000 per kilogram of body weight. It is highly probable that this concentration is sufficient for the destruction of spirochetes in the blood, while in the tissues the drug is probably cumulative in action until a concentration is reached at which spirocheticidal effects are produced; in in this manner, the administration of small doses of bismuth results in the accumulation in the tissues of curative amounts, since elimination is always slower than absorption when the tartrobismuthates are given human beings or the lower animals in amounts of approximately 0.002 to 0.005 gm. per kilo every 5 to 7 days which corresponds to about 0.1 to 0.2 gm. for the average human adult.

The spirocheticidal activity of bismuth being at least four times greater than mercury permits the administration of sufficient amounts to bring about more rapid curative effects in acute early syphilis than is ordinarily the case with mercury and in such cases I believe that bismuth is the remedy of choice if for any reason arsphenamin, neoarsphenamin or their substitutes cannot be given. In my opinion bismuth probably accumulates in syphilitic tissues to a greater extent than in non-infected tissues and in this manner the amount of bismuth ions reaches a spirocheticidal concentration in these areas, even though the amount in the blood may be below this level. Of course, the drug is being constantly eliminated, but by proper dosage it is possible to maintain the spirocheticidal concentration in the spirocheta infected tissues without damaging the kidneys, liver and gastro-intestinal tract with excessive amounts.

Just how bismuth destroys *Spirochæta pallida* is not known. It may be that the metal unites with and precipitates the proteins of the parasites which results in their death, followed by digestion by enzymes from the parasites themselves, the tissue fluids or tissue cells. This mechanism is just as obscure as the whole subject of the mechanism of the destruction of microparasites by germicides.

Other Pharmacological Effects of Bismuth.—Aside from studies upon the absorption and elimination of bismuth summarized above and the toxicological effects to be considered in the succeeding chapter, little more is known of the pharmacology of bismuth. We do not have any information, for example, concerning its influence upon blood pressure, the chemistry of the blood, kidney function, etc., as discussed in Chapter XLIII in regard to

arsphenamin and neoarsphenamin. Fournier and Guénot noted temporary polyuria and albuminuria in a few cases treated with intramuscular injections of the tartrobismuthates, but never any persistent disturbance of renal function; evidently the diuretic effect is similar to that sometimes produced by mercury. No doubt, if bismuth becomes widely employed in the treatment of syphilis, studies in these subjects will be made owing to their very useful and practical importance.

Mention may be made here of the blood changes produced by bismuth as reported by Betz.[15] Examinations were made by 25 cases in the primary and secondary stages, before and after each injection. As a general rule a mild and temporary degree of leukocytosis followed each injection, especially in the beginning of treatment, due to an increase of the neutrophils and eosinophils and in the later stages to an increase of lymphocytes. In some cases the erythrocytes were increased, while in a few, however, there were evidences of erythrocytic destruction with anisocytosis but with no evidences of poikilocytosis. Evidently these effects upon leukocytes, erythrocytes and hemoglobin were due primarily to the action of bismuth on the bone marrow, which may temporarily stimulate its functions or, in large doses, exert a toxic depressive effect with blood destruction.

CHAPTER LV

TOXICOLOGY OF BISMUTH IN RELATION TO METHODS OF ADMINISTRATION AND THE TREATMENT OF SYPHILIS

From the standpoint of the treatment of syphilis with bismuth most interest is to be placed in the toxicological effects produced by intramuscular and intravenous injections of various organic and inorganic salts and especially of the tartrobismuthates. A knowledge of these untoward effects is imperative for the treatment of syphilis with bismuth and these compounds cannot be given by rule since the toxic effects vary in different patients and some individuals are more susceptible than others.

General Toxicology of Bismuth.—Instances of chronic poisoning from the application of dusting powders and salves of bismuth subnitrate to wounds are not lacking, since first described by Kocher[1] in 1882; Mayer and Baehr[2] have collected 42 such cases up to 1912, 13 of them being fatal intoxications. In addition to these chronic poisonings a number of cases of acute poisoning first reported by Benneke and Hoffman[3] in 1906, have been recorded following the internal administration of bismuth subnitrate for roentgenographic purposes. In some of these at least, poisoning has been due to the absorption of contaminating nitrites instead of bismuth and since the adoption of the carbonate of bismuth and other precautions for *x*-ray work the danger of poisoning from these has been removed. Chronic bismuth poisoning has also followed the use of Beck's paste, Mayer and Baehr having collected 19 cases from the literature and adding 3 of their own, one of which had a fatal outcome following the injection of three ounces of a 25-per cent. bismuth paste into a sinus for roentgenographic purposes.

Undoubtedly the widespread use of the tartrobismuthates, bismuth hydroxid and other organic and inorganic salts in the treatment of syphilis will result in greatly renewing clinical interest in bismuth poisoning and, since it is essential for the physicians to be acquainted with the lesions and symptoms of this intoxication, the subject is here considered from the standpoint of intramuscular and intravenous routes of administration in relation to the treatment of syphilis.

Chemistry of Bismuth Compounds in Relation to Toxicity and Therapeutic Activity.—During the past four years a large number of new compounds of bismuth have been proposed for the treatment of syphilis and especially organic salts, but little is known of the relationship of their chemical constitution to toxicity for the host (organotropism) and toxicity for the spirochetes (parasitropism). The ordinary salts, as the subnitrate and subgallate, have been found too inert, although they have not been extensively employed by intramuscular injection. At the present time the tartrobismuthates of sodium or potassium and colloidal suspensions of the hydroxid, are most popular for the treatment of syphilis. Insofar as chemical constitution is concerned, I believe that the ease and rapidity with which the bismuth ions are dissociated after administration will prove the important factor as is apparently true of mercury compounds; of importance likewise are the amounts of bismuth in the compounds and their solubility in the tissues and absorbability after administration. Doubtless further chemical research will result in evolving compounds of lesser toxicity and especially by intravenous injection, but these are likewise apt to be of lesser therapeutic activity since the reduction in toxicity is likely to be based upon a decreased power of dissociation of bismuth ions, which I believe is the important factor in relation to both organotropism and parasitropism.

Toxicity of Bismuth for the Lower Animals by Intramuscular and Intravenous Administration.—Before discussing the tissue changes and symptoms of bismuth poisoning in human beings, it may be well to briefly review the effects observed among the lower animals in experimental intoxications. As far back as 1886, Steinfield and Meyer[4] injected bismuth oxid subcutaneously into frogs, rabbits, cats and dogs and produced two types of poisoning; about one year later, Dalche and Vallejean[5] observed similar results following subcutaneous injections of bismuth subnitrate into dogs. These experiments showed that sufficient amounts of bismuth could be absorbed from the subcutaneous tissues to produce toxic lesions and symptoms and confirmed the clinical observations of Kocher and others.

Since the introduction of bismuth into the treatment of syphilis by Sazerac and Levaditi in 1921, several investigators have studied the toxicity of various organic and inorganic compounds for the lower animals, and chiefly the rat, guinea-pig and rabbit to determine the relative toxicity of these compounds by intramuscular and intravenous injection, as based upon the smallest amounts producing immediate death (*dosis lethalis*) or the largest amounts tolerated over one or two weeks (*dosis tolerata*). No attempt was made in tests of this kind to reproduce the characteristic symptoms of bismuth poisoning in man, but they are not without value as indices of the relative toxicity of different compounds by different routes of administration and likewise reproduce for histological study the various tissue changes that may be engendered.

The results of some tests of this kind have already been briefly referred to in Chapters XV and XXV. Most interest has been placed in potassium and sodium tartrobismuthate, because this salt has been especially recommended by French physicians for the treatment of human syphilis; recently Pacella[5] reported the results of a series of studies upon the toxicity of this tartrobismuthate for frogs, guinea-pigs and rabbits. Levaditi and Sazerac have found that the minimal toxic dose of water soluble sodium and potassium tartrobismuthate (luatol) for rabbits by intravenous injection was about 0.010 grams per kilo and about 0.050 grams per kilo by intramuscular injection. Myers and Corbitt,[7] however, found that the maximum tolerated dose of "luatol" for white rats by intravenous injection was 0.036 grams per kilo for a period of seven days and that compounds prepared by them were tolerated in dose of 0.050 grams per kilo by intravenous injection. Of course, it is to be expected that differences in the percentage of bismuth in the compounds tested, concentration of the solutions, rapidity of injection, kind of animal employed, condition of the animals, etc., would be factors modifying the results of toxicity tests by different investigators as discussed more fully in Chapter II. Myers and Corbitt, however, employed the same technic as is used for determining the toxicity of arsphenamin and neoarsphenamin and I have employed the same method in my toxicity tests with water soluble tartrobismuthates. In my experiments white rats were injected intravenously with graded amounts of the tartrobismuthates in solution, the rate of injection being 1 c.c. in two minutes, etc., exactly as described in Chapter II for the testing of the organic arsenical compounds. With these tests the minimal lethal and maximum tolerated doses were ascertained. In addition, I have determined the maximum tolerated doses of the water-soluble tartrobismuthates for rabbits by the intravenous injection of multiple small doses as one would employ for the treatment of syphilis; also, the maximum tolerated doses of water-soluble and oily suspensions of the tartrobismuthates by intramuscular injection of multiple small doses comparable to those administered by this route for the treatment of syphilis.

In these experiments "luatol" or the water-soluble sodium and potassium tartrobismuthate and "trepol," the suspension of the same compound in a vegetable oil, both of French manufacture, were employed; sodium tartrobismuthate, potassium tartrobismuthate and bismuth trioxid were kindly prepared and furnished me by Dr. George W. Raiziss.

(*a*) *The Minimal Single Lethal Doses of the Tartrobismuthates by Intravenous Injection.*—As previously stated, white rats of 100 to 150 grams kept under standard conditions were employed, the injections being given in a femoral vein at the rate of 1 c.c. per two minutes of 1 per cent. solutions; the smallest amounts producing immediate or almost immediate and fatal effects were approximately as follows:

Sodium and potassium tartrobismuthate (41.5% Bi).	0.090 grams per kilo
Sodium tartrobismuthate (59.08% Bi).....	0.090 grams per kilo.
Potassium tartrobismuthate (61.32% Bi).....	0.095 grams per kilo.

(*b*) *The Maximum Single Tolerated Doses of the Tartrobismuthate by Intravenous Injection.*—At the same time, the maximum single tolerated doses of these compounds for white rats by intravenous injection were determined, the results being approximately as follows on the basis of survival for a period of fourteen days:

Sodium and potassium tartrobismuthate.....	0.024 grams per kilo.
Sodium tartrobismuthate.....	0.018 grams per kilo.
Potassium tartrobismuthate.....	0.020 grams per kilo.

It will be noted that the quartenary compound sodium and potassium tartrobismuthate was tolerated in slightly larger amounts than the sodium or potassium tartrobismuthates, probably because the former contained less bismuth than the latter two compounds. Of course, the doses mentioned are not absolute as slightly varying results were observed due to variations in the susceptibility of different rats of approximately the same weight and general condition on the same diet. As stated in Chapter II, it is not possible to render the results of biological tests of this kind mathematically correct, but the above values are approximately correct and state the average toxicity of these compounds by intravenous injection. It is to be noted in passing, however, that the tartrobismuthates are from three

to four times less toxic than some of the soluble mercurials, as the bichlorid and benzoate; from the standpoint of absolute toxicity based upon tests of this kind, there should be no objection to the intravenous injection of the soluble tartrobismuthates in the treatment of syphilis in dose of 0.010 grams per 60 kilos or 132 pounds, which is approximately one-sixth of a grain, ten to twenty times less than the amount injected intramuscularly, and at least 100 times less than the maximum tolerated dose by intravenous injection per kilo of body weight if the tissues of the rat and human being are equally susceptible.

(*c*) *The Maximum Tolerated Doses of the Tartrobismuthates by Repeated Intravenous Injections.*—Of more interest from the standpoint of intravenous therapy have been the results of multiple intravenous injections in rabbits. These animals received increasing doses of 0.0005 to 0.008 grams per kilo every day until fatal intoxication occurred. The following number of injections were required to produce emaciation, nephritis and death:

Sodium and potassium tartrobismuthate (luatol), 39 to 43 injections or a total of 0.133 to 0.197 grams per kilo.

Sodium tartrobismuthate, 38 to 40 injections or a total of 0.117 to 0.149 grams per kilo.

Potassium tartrobismuthate, 39 to 40 injections or a total of 0.133 to 0.149 grams per kilo.

(*d*) *The Maximum Tolerated Doses of the Tartrobismuthates and Bismuth Trioxid by Repeated Intramuscular Injections.*—In the treatment of syphilis, the soluble tartrobismuthates dissolved in water or the insoluble salts suspended in a vegetable oil are ordinarily administered in dose of 0.2 grams by intramuscular injection every 5 days for 10 to 15 doses or until 2 to 3 grams have been given. For the adult of average weight this dose corresponds to 0.004 grams per kilo or a total of about 0.05 grams per kilo. Guinea-pigs, however, have withstood a series of 16 to 18 injections at intervals of 3 to 4 days of sodium and potassium tartrobismuthate in water (luatol) and suspended in oil (trepol) until as much as a total of 0.224 grams per kilo had been given without succumbing although loss in weight and pathological tissue changes in the internal organs were produced. Similar results were observed with sodium tartrobismuthate dissolved in water and suspended in olive oil; also potassium tartrobismuthate in water and olive oil and bismuth trioxid suspended in olive oil.

As a general rule, however, the solutions in water were slightly more toxic and doubtless were more rapidly absorbed than suspensions in olive oil; very probably the rate of dissociation is the same after absorption occurs and differences in toxicity are to be ascribed primarily to variations in the rate of absorption. Suspensions of bismuth trioxid, however, were slightly less toxic even though this compound contains a higher percentage of metallic bismuth, due primarily to slower absorption and dissociation of this compound as compared with the water-soluble tartrobismuthates.

Toxicity of Bismuth Compounds for the Lower Animals in Relation to Toxicity for Man.—While sufficiently extensive studies on the comparative toxicity of the organic and inorganic compounds of bismuth for the lower animals have not been made to warrant definite statements, yet data at hand indicates that the toxic effects of intramuscular injections are in relation to the amount of bismuth in the compound, the rate of absorption and probably the degree of dissociation of the bismuth ions. As is true of the mercurials, those compounds containing most bismuth are in general terms the most toxic, but the relation is not constant since a compound containing less bismuth may still be more toxic if it is more rapidly absorbed. Comparative toxicity, therefore, is a matter of absorption and dissociation of the bismuth regardless of whether the compound is a finely divided preparation of the metal itself, an inorganic or organic salt. Rate of absorption and dissociation from the muscles or subcutaneous tissues are in turn not only influenced by the menstrum employed, but likewise by the rate of solubility in the tissue juices as well as by the degree of local irritation; compounds eliciting marked inflammatory reactions are probably not absorbed as rapidly as those which do not.

When a bismuth compound is injected intravenously other factors enter into the mechanism of toxicity in addition to that of the rate of dissociation of bismuth ions; some of these factors are agglutination and hemolysis *in vivo* with the possibility of production of emboli, which I will discuss more fully later in this chapter. Here it may be stated, however, that while the experiments summarized above indicate that the soluble tartrobismuthates may be

given intravenously yet the injection of these or of colloidal preparations of bismuth hydroxid may elicit immediate reactions in the blood tending to increase the chances of untoward toxic reactions in human beings.

Toxicity tests in the lower animals are of distinct value, but do not show all the toxic phenomena that may be observed in human beings; for example, they may fail to show salivation and gingivitis in chronic intoxications and cough, thoracic oppression, general muscular pains, local pain at the site of injection, etc., which may develop in human beings treated with bismuth by intravenous injection.

Pathological Tissue Changes Produced by Bismuth in the Lower Animals.—Toxicity tests with the lower animals have aided greatly in a study of the histological changes produced by bismuth and no chemotherapeutic study can be regarded as complete that does not include an investigation of the possible tissue changes that a drug may produce and especially in the chief organs of elimination as the liver and kidneys, even though toxic symptoms are not elicited or demonstrable.

Bismuth is no exception to this rule and the pathological changes that may be produced in the physiologically important organs are of paramount interest and value, especially those that may be produced by the repeated injection of doses per kilo of weight comparable to those given human beings. Investigations of this kind are especially valuable for teaching us the minor changes that may occur before manifest lesions and symptoms are developed and tests among the lower animals are of value in this connection even though conditions in the syphilitic human subject may be altered and different by reason of additional pathological changes engendered by *Spirochæta pallida*.

Lucke and Klauder[8] have studied the changes in the kidneys and liver of rabbits following the administration of single lethal doses of the tartrobismuthates and bismuth trioxid with the general result that *renal injuries* involved chiefly the epithelium of the convoluted tubules. These showed all types of degeneration, ranging from severe cloudy swelling to extreme necrosis and marked calcification. The glomeruli did not appear primarily damaged, and often were found to be well preserved in the midst of completely necrotic tubules. The glomerular capillaries frequently contained partly conglutinated and sometimes hyalinized masses of erythrocytes. The glomerular spaces were usually free from foreign material. The *lesions in the liver* were much less conspicuous. There was usually present a definite cloudy swelling, with evident nuclear degeneration, and the appearance of minute fat droplets. Occasional small foci of necrosis flooded with erythrocytes and invaded by a few mononuclear and polynuclear leukocytes were found in most animals.

These effects were, therefore, quite similar to those produced by mercury (Chapter LIII), although the doses were very large being equivalent to from 9.0 to 30.0 grams per kilos or 132 pounds by intramuscular injection and from 0.6 to 1.8 grams by intravenous injection or at least 50 to 200 times larger than the amounts administered to human beings at one time. Kollert, Strasser and Rosner[9] injected "trepol" (an oily suspension of sodium and potassium tartrobismuthate) into rabbits and the kidneys showed a swelling of the tubular epithelium causing complete obstructions in some cases. There was also exfoliation of finely granular epithelial cells with cylinder formation producing in short, a type of degenerative lesion similar, in the opinion of the author, to the mercurial nephrosis described by Volhard and Fahr.

In connection with the toxicity tests with the tartrobismuthates and bismuth trioxid employing rats, guinea-pigs and rabbits described above, Dr. Lucke and myself have also made macroscopic and microscopic studies of the principal organs and the results have been as follows:

(*a*) The intramuscular injections of guinea pigs every 3 to 4 days with 0.010 to 0.013 grams per kilo for 11 to 17 doses, corresponding to 0.6 to 0.8 gm. per 60 kilos or approximately

3 to 4 times the amounts given at one time to human adults, produced relatively slight histological changes. In the *kidneys* the cells of many of the convoluted tubules were swollen, very granular, vacuolated, anuclear, and desquammated, but massive necroses were not found. The glomeruli were practically normal. The *liver* cells, in general, were in a state of mild cloudy swelling and very occasionally small foci of necroses were encountered. These effects were produced by all of the compounds studied, namely, sodium and potassium tartrobismuthate in water (luatol) and in oil (trepol), potassium tartrobismuthate in water and oil, sodium tartrobismuthate in water and oil and bismuth trioxid in oil. They have shown, therefore, that the bismuth salts are very much less renotropic and hepatotropic than the soluble and insoluble salts of mercury and practically no histological changes at all were observed in the other organs studied as the adrenals, heart, lungs, spleen and brain.

FIG. 28.—KIDNEY CHANGES PRODUCED BY BISMUTH.
Necrosis and calcification of the spiral tubules of the kidney of a rabbit after 46 daily intravenous injections of sodium and potassium tartrobismuthate (luatol).

(*b*) But in sharp contrast with these relatively mild histological changes produced by intramuscular injections are the rather severe changes produced by *intravenous injections* of the soluble salts and these changes constitute the chief reason for not administering these compounds intravenously except in very small doses. Single lethal or maximum tolerated doses of sodium and potassium tartrobismuthate (luatol), potassium tartrobismuthate and sodium tartrobismuthate produced marked degeneration and necrosis of the epithelium of the convoluted tubules (Fig. 28) with calcareous deposits when the animals survived 3 days or longer. The glomerular loops were frequently blocked by agglutinated erythrocytes, the endothelial nuclei of the tufts were pyknotic and considerable albuminous precipitate occupied the capsular spaces. The liver lesions were generally less extensive but sometimes severe (Fig. 29) and consisted of small areas of focal necrosis, some of which were invaded by leukocytic and monocytic phagocytes, the liver cells in general being

granular and containing numerous hydropic and fatty vacuoles. In the other organs studied (brain, heart, lungs, adrenals and spleen) the changes were inconspicuous and consisted chiefly of capillary emboli of agglutinated erythrocytes and inconspicuous cloudy swelling.

Multiple daily intravenous injections of all three compounds for about 40 injections and totalling approximately 0.117 to 0.149 grams per kilo, produced even more severe changes and particularly of the kidneys and liver. In the former the epithelium of the convoluted tubes was necrotic, desquammated and heavily infiltrated with calcium salts. The inner third of the cortex and that portion of the boundary zone which contains the spiral tubules were particularly involved. The glomerular changes consisted of occlusion of some of the loops by hyalinized erythrocytes and a moderate amount of albuminous precipitate was present in the capsular spaces. In the liver there were occasional areas of necrosis and in

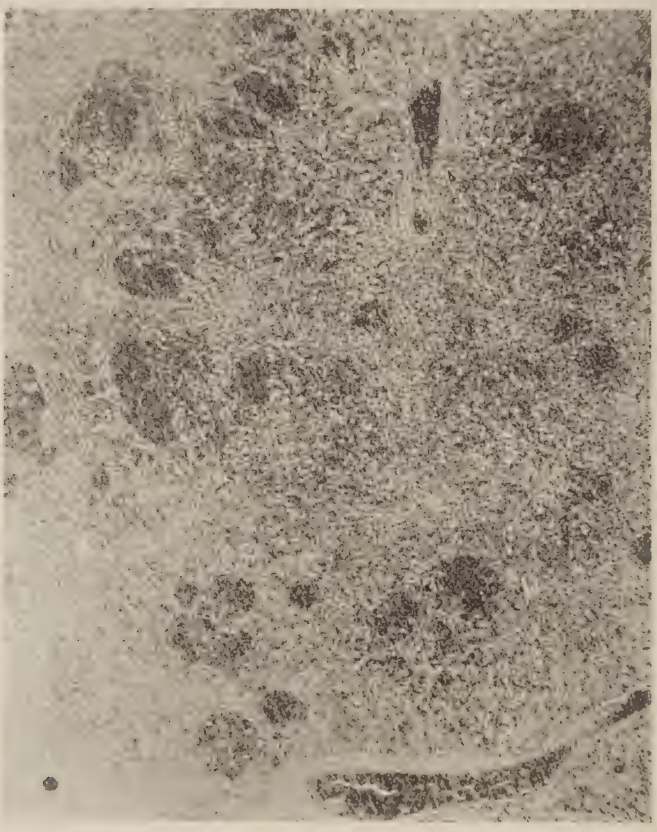

FIG. 29.—LIVER CHANGES PRODUCED BY BISMUTH.

Hemorrhagic and necrotic foci of the liver of a rabbit twenty-four hours after the intravenous injection of 0.060 gm. per kilo of sodium tartrobismuthate.

some instances a few of the bile ducts and portal canals had undergone complete necrosis. The liver cells in general contained an increased number of albuminous granules, were much vacuolated, and often presented nuclear degenerations. Myers and Corbett[10] in a study of the toxicity of several soluble and insoluble salts, found the toxicity greater for the soluble compounds, although the rate of absorption was found to be quite variable for all. In their animals emaciation was one of the first symptoms and histologically, destructive changes were found in the kidneys and liver along with discoloration of the intestinal mucosa, when large doses were administered.

Clinical Significance of the Chemopathological Tissue Changes Produced by Bismuth.—These investigations have shown, therefore, three important

facts, namely, (1) That intramuscular injections of bismuth are very much less toxic than intravenous injections and the lesions produced by the latter are so severe that great caution is required when the soluble salts are given intravenously; (2) that the histological injuries are practically the same for all three of the tartrobismuthates studied either dissolved in water or suspended in olive oil and (3) that bismuth is most toxic for the kidneys, next for the liver and relatively non-toxic for the brain, heart, lungs, adrenals and spleen.

I have not any opportunities for studying human tissues from fatal cases of bismuth poisoning, but believe that essentially similar changes may occur. Furthermore, it must never be overlooked that the pathological changes in human beings produced by *Spirochæta pallida* or other infections may materially reduce tolerance and enhance toxic effects by the drugs. In the treatment of syphilis with bismuth the same care must be exercised in relation to the kidneys as when mercury is administered and especially if arsphenamin or one of its substitutes is administered after a course of bismuth. But unquestionably bismuth is less toxic than the ordinary soluble and insoluble salts of mercury; I would judge that the toxicity is at least 4 or 5 times less and when it is remembered that bismuth is 4 or 5 times more spirocheticidal than mercury it is not difficult to understand that bismuth deserves a place in the therapy of syphilis and especially of late or chronic syphilis.

Symptoms and Lesions of Bismuth Intoxication in Relation to the Treatment of Syphilis.—Investigations with the lower animals have shown, therefore, that the administration of very large amounts of bismuth by intramuscular or intravenous injection may result in the production of tissue changes, particularly in the kidneys and liver, similar to those produced in poisoning with the organic and inorganic compounds of mercury. In my opinion these effects do not necessarily indicate a special tissue affinity of bismuth for renal epithelium and the liver; rather, it would appear that these tissues are injured by reason of their eliminative functions since so much bismuth is excreted through the urine and bile. With ordinary doses of the tartrobismuthates and other compounds of bismuth injected intramuscularly in the treatment of syphilis, the urine is usually free of albumin and erythrocytes indicating that under proper conditions kidney irritation is not ordinarily encountered, but I shall discuss this subject shortly in more detail.

At this writing I do not know of any fatal cases of bismuth poisoning following the intramuscular administration of the tartrobismuthates or other compounds in the treatment of syphilis although sudden deaths have followed intravenous injections as reported by Magnus;[10a] but the lesions described above produced by these compounds in the lower animals were quite similar to those observed in human beings succumbing to bismuth poisoning from the use of bismuth in dusting powders and paste for surgical purposes, as reported by Maher and Baehr,[11] Higgins[12] and others. In other words excessive doses of the tartrobismuthates and other bismuth compounds may produce serious or fatal poisoning in human beings and exactly the same care should be exercised in dosage and intervals of injection as demanded in the administration of mercury to avoid accumulative effects and serious tissue injury.

Etiological and Clinical Classifications of Toxic Reactions.—From the etiological standpoint, toxic reactions are, of course, due primarily to the bismuth administered as the amounts injected intramuscularly or intravenously are too small to warrant serious consideration of toxic reactions

being produced by impurities. But the condition of the patient may contribute in an important manner to the production of toxic reactions, as is true of mercury; for example, if the mouth and gums are in bad condition there is predisposition to siderosis, gingivitis and stomatitis. If the patient is subject to gastro-intestinal disorders, there is predisposition to diarrhea, colic, etc. It is likewise probable that focal infections of the teeth, tonsils and other tissues may predispose to bismuth dermatitis, as in the case of the arsenicals and finally, some individuals appear to possess a natural hypersensitiveness to bismuth so that even very small doses cannot be given These various factors may be summarized, therefore, somewhat as follows:

Etiological classification of reactions
1. Due to the drug.
2. Due to route of administration.
3. Due to predisposing pathological states of individual patients.
4. Due to hypersensitiveness to bismuth.

The toxic reactions that may follow the administration of bismuth are likewise of a varied character. When intravenous injections are given there may occur an acute reaction apparently due to colloidal shock and analogous to similar reactions produced by intravenous injections of other heavy metals; in addition, accidental intravenous injections of suspensions in the course of intramuscular injections may produce symptoms of pulmonary embolism. Siderosis, halitosis, ptyalism, gingivitis, stomatitis and other gastro-intestinal disturbances are most commonly observed; various skin eruptions, renal irritation and provocative Herxheimer reactions are less commonly observed. Local reactions due to muscle irritation and necrosis, may accompany intramuscular injections, the whole subject being briefly classified as follows:

Clinical classification of reactions
1. Acute colloidal shock reaction from intravenous injections.
2. Embolism due to accidental intravenous injections.
3. Nutritional disturbances.
4. Skin eruptions and jaundice.
5. Siderosis, halitosis, ptyalism, stomatitis, and other gastro-intestinal disturbances.
6. Irritation of kidneys.
7. Herxheimer reactions.
8. Local tissue reactions.

General Toxic Effects of Bismuth.—In my experience the earliest symptoms of untoward effects following the intramuscular injection of the tartrobismuthates are general aches in the muscles and joints accompanied by some lassitude and loss of appetite. As a rule, these effects are not severe enough to cause cessation of treatment, and in some instances at least may be due to provocative effect of bismuth on the spirochetes and especially in the case of such lesions as painful lymphatic glands and pain in the heart due to the presence of syphilitic infection of these tissues. At the same time, there is usually some tenderness of the muscles at the site of injection; this symptom varies greatly, however, in different individuals and according to the kind of mixture injected and site of injection.

Acute Colloidal Shock and Embolism Reactions from Intravenous Injections. The intravenous injection of the water-soluble sodium and potassium tartrobismuthate and colloidal bismuth hydroxid, however, have been followed in some instances by acute symptoms of dizziness, pallor, rapid and weak pulse, dyspnea, convulsions and collapse, which are suggestive of a colloidal shock reaction or embolism the result of intravascular agglutination and the production of serum precipitates. Sazerac and Levaditi have strongly

advised, therefore, against the intravenous injection of bismuth on account of these dangers attending its use and if bismuth is administered by this route, the drug should be diluted with at least 10 to 20 c.c. of sterile saline solution and injected very slowly.

In addition to these reactions, the injection of 0.1 to 0.2 grams of the tartrobismuthates suspended in oil into the gluteal muscles has in some exceptional instances been followed in twelve to twenty-four hours by intense aches and pains in the larger bones, joints and muscle groups accompanied by chilliness, fever, a feeling of tightness or compression of the thorax and dyspnea as reported by Shivers.[13] These symptoms are suggestive of embolism due to accidental piercing of a vein, but in the three cases reported by Shivers it was reasonably certain that this accident did not occur and, furthermore, the symptoms did not develop immediately as may be expected if accidental embolism had been produced. The *rheumatoid pains* are especially characteristic and may affect the ribs, spine and particularly the legs as reported by Decrap,[14] Casal[15] and others. They are apt to be continuous, spontaneous and unvarying during the day; they apparently are not influenced by age, sex, stage of syphilis or exercise and are due rather to periosteal intolerance than to Herxheimer reactions.

Chilliness and fever accompanied by rapid pulse and some sweating occurring a few hours after intramuscular injections of bismuth have been described; I have not observed such reactions but it is possible that in exceptional instances the intramuscular injections may produce sufficient irritation and even necrosis of the tissues to engender a protein reaction of this type—a form of non-specific protein reaction produced by the products of tissue necrosis.

Nutritional Disturbances.—In addition, Ducrey[16] has described loss of weight and asthenia as a result of prolonged bismuth treatment in syphilis. I have likewise observed some loss of weight which was attributed to loss of appetite with the appearance of bad taste, foul breath and a blue line of the gums after eight or more injections of 0.2 grams of potassium tartrobismuthate in oil had been given, but as a general rule a course of twelve such injections at intervals of 5 to 7 days were without any general untoward effects.

Bismuth Skin Eruptions.—In the majority of instances no other general untoward effects are observed or complained of following the intramuscular injection of the tartrobismuthates unless stomatitis develops and the injections are continued; under these conditions gastro-intestinal and kidney lesions may be produced and in exceptional instances pruritus and *cutaneous eruptions* may develop, as in the case of exfoliative dermatitis reported by Pinard and Marassi.[17]

Hudelo[18] has reported a case of bismuth stomatitis with cutaneous erythroderma and mentions a case of Gastou and Pontoisseau that received three intravenous injections of colloidal bismuth in five days, which was followed by a confluent and generalized papulo-squamous erythema. Hudelo cites another case reported by Lortat-Jacob and Roberti in which the patient had never received any arsenic and developed an erythema scarlatiniforme from bismuth injections. Levy-Frankel has reported a case of scarlatiniform erythema with purpura after two injections of the iodobismuthate of quinine. Galliot[19] has reported bismuth urticarial eruptions in two women and a scarlatiniform eruption on an infant's buttock on the side of the injection. Lepinay[20] has reported a man that received neo-arsphenamin and grey oil without any reaction and two months later was given one injection of the iodobismuthate of quinin. Large urticarial plaques with pruritis of the

back, fever and headache occurred the next day. Nicolas[21] has reported a bismuth lichenoid eruption and a localized eczema, also a rubeoliform and discreet purpura of the extremities that Fournier and Guénot mention. Lehner[22] has reported a tabetic that developed a toxic erythema with herpes zoster of the right thigh after bismoluol. This patient was also sensitive to other bismuth salts, as shown by intracutaneous tests. Sarateanu[23] has also recorded a case of general erythrodermia from injections of neotrepol and Freudenthal[23a] has recently described three interesting cases presenting local exanthems due to embolism following intragluteal injections of bismuth.

Bismuth Jaundice.—I have never seen a case of jaundice due to injections of the tartrobismuthates and this condition is apparently a very uncommon accident in bismuth therapy of syphilis. Hudelo and Rabut[24] state that it may occur, but rarely, and that bismuth may be given to cases recovered from arsphenamin jaundice without danger of recurrence. As previously stated histological studies have shown that the liver is not involved, except in severe bismuth intoxications from intravenous injections.

Bismuth Siderosis and Halitosis.—Probably the earliest untoward effects produced by intramuscular injections of bismuth tartrobismuthate are local irritation and a slight degree of general muscle aches and some loss of appetite, the development of a bad taste, coated tongue, disagreeable odor of the breath and a blue line (siderosis) along the margins of the gums. Sometimes the *halitosis* or odorous breath precedes the appearance of the blue line, but generally both develop at the same time and forecast the appearance of stomatitis and are associated with it. While the breath is disagreeable and the patient may be conscious of a bad taste in the mouth, fetor is not present as in mercurialism unless a well marked stomatitis is present.

The *blue line* first appears on the gingival margin of the incisor teeth, both anteriorly and posteriorly, and may later spread if treatment is continued. It is indistinguishable from that seen in plumbism and develops in the majority of patients after ten or more intramuscular injections of the tartrobismuthates in dose of 0.1 to 0.2 grams in oil every four or five days. Some individuals are more susceptible than the average and may show a blue line after three or four injections. According to Azoulay[25] histological examination of the gums impregnated with bismuth shows that the drug is eliminated only on the dental side of the gums. Milian and Perion[26] state that the pigmentation is due to the presence of bismuth particles in the papillæ of the dermis and especially in the endothelial cells of the capillaries where they are carried by the blood. According to Meyer and Steinfield sulphids of bismuth are produced and it is believed that the deposits may be so heavy as to cause obliteration of the vessels and consequent necrosis with the production of ulcers.

Blue spots may also appear under the tongue and in the buccal mucosa of the cheeks. Evidently this pigmentation of both gums and buccal mucosa is due primarily to depositions of bismuth, as shown by Klare[26a] and others, brought to these tissues for elimination and it is entirely likely that similar changes occur in the mucosa of some parts of the intestines and especially of the first portion of the colon, responsible for the constipation and anorexia sometimes accompanying this condition.

As a general rule the blue line and spots tend to disappear rapidly after cessation of treatment; Milian states that they may disappear in five to fifteen days and Klauder[27] has observed their disappearance in a month after stopping treatment.

Bismuth Gingivitis, Stomatitis, Ptyalism and Other Gastro-intestinal Disturbances.—If the administration of bismuth is continued in full dosage after

the development of a blue line of the gums, gingivitis may be produced. Ordinarily this is a mild localized inflammation which tends to disappear in a few weeks when treatment is interrupted, but severe gingivitis and stomatitis may be produced as reported by Chatelein and Hude[27a] and others. Changes of this kind are exceptional among subjects whose gums are healthy and sound and who are careful in maintaining a proper hygienic condition of their mouths. On the other hand, among individuals with soft, spongy, bleeding and tender gums with tartar deposits, bismuth gingivitis is apt to be more severe and generalized owing to the fact that bacteria and spirochetes add to the irritation and inflammatory changes.

The gingivitis is apparently caused by the depositions of bismuth in the walls of the capillaries causing partial obliteration with resulting congestion and loss of nutrition and the production of minute ulcers. These ulcers develop, therefore, in the areas of most intense pigmentation and are surrounded by greyish-blue borders of bismuth deposits. Bacteria then add to the inflammatory changes and Azoulay believes that the fusiform bacillus and spirochete of Vincent are especially likely to produce severe ulceration under these circumstances with the development of greyish exudates and false membranes. In such cases the submaxillary and other neighboring glands become swollen and painful by reason of this secondary bacterial infection. In a few cases of severe bismuth stomatitis which I have had the opportunity of examining bacteriologically, enormous numbers of fusiform bacilli and spirochetes were found as described by Azoulay, along with other various other bacteria.

In exceptional cases gingivitis is followed or accompanied by generalized stomatitis but only among patients whose gums and teeth are in very bad condition, or who are subject to gastro-intestinal disturbances with frequent shallow irregular ulcers on the sides of the tongue or of the buccal mucosa. The symptoms resemble those of mercurial stomatitis with foul breath, painful mastication, anorexia and malaise but the ulcers tend to heal more rapidly after bismuth injections are stopped.

Ptyalism is unusual in bismuth gingivitis, occurs only in well-marked cases and even then is moderate and not nearly as severe as in mercurial gingivitis and stomatitis. While ptyalism is usually an early sign of impending mercurial gingivitis this is not the case in bismuth gingivitis and the physician must not depend upon the development of this sign as the first indication of over-dosage; rather the gums should be inspected at least once every week for the blue line as the earliest sign of untoward effects.

Since the production of gingivitis and stomatitis is due to the metal bismuth itself, one naturally expects that these effects vary according to the bismuth content, solubility and dosage of the compound injected. Injections every 2 or 3 days of any bismuth preparation is more apt to produce discoloration and inflammation than when given at intervals of 5 to 7 days, owing to the bringing of more bismuth to the mouth for elimination than the tissues can excrete. A single dose of 0.5 grams of the tartrobismuthates is almost sure to produce gingivitis according to Levaditi, Milian, Azoulay and others whereas in doses of 0.1 to 0.2 grams at intervals of 5 days as much as twelve to fifteen injections totalling 2 to 3 grams may be given without bad effects. With these doses the blue line may be produced but severe gingivitis is exceptional, as shown by the experience of Milian and Perin.[28] Apparently, the balance of the gastro-intestinal tract does not suffer nearly as much as the mouth during the elimination of bismuth. Milian[29] and Azoulay[30] have reported cases of severe enteritis and *ulcerative colitis* but these are quite rare.

The tongue may be streaked and the patient may complain of nausea, anorexia and constipation but ordinarily no other effects are noticed and even these do not usually develop. No doubt bismuth is also eliminated through the intestinal mucosa and especially that of the colon in much the same manner as in the mouth and very probably the mucosa may be discolored, but severe inflammation and ulceration does not develop during the treatment of syphilis with bismuth due to the small doses ordinarily injected at intervals of 3 to 7 days and more especially because the intestinal mucosa is ordinarily in a healthy condition without predisposing bacterial injuries as are so common in the mouths of adult individuals. For this reason I believe that preexisting gingivitis or pyorrhea is the most important single factor predisposing to the development of bismuth gingivitis and stomatitis during the treatment of syphilis with bismuth and mercury.

Effect of Bismuth upon the Kidneys.—While as previously stated bismuth may produce tubular nephritis when administered to the lower animals (rabbits and rats) in single massive doses, yet bismuth is not nearly as likely to produce renal irritation as mercury. *Polyuria* may be observed in exceptional instances as stated by Fournier and Guegnot,[31] but this sign of renal irritation is not nearly as common as follows the administration of mercury; in my experience patients treated with intramuscular injections of 0.1 to 0.2 grams of potassium tartrobismuthate every 5 to 7 days rarely observe an increase of urine and the measure of a series of 24 hour outputs has not usually shown an increase above the normal fluctuations observed before bismuth treatment was begun.

Albuminuria has been reported by Simon and Leoy-Buig,[32] Fischer[32a] and others due to the administration of bismuth in the treatment of syphilis, but this sign of renal irritation is observed only in exceptional cases and Azoulay states that neither albuminuria nor cylindruria develop after the intramuscular administration of "trepol" (a suspension of sodium and potassium tartrobismuthate in oil). Hudelo and Rabut[33] state that they have observed albuminuria only 4 times in 10,000 injections of bismuth. Klauder observed only a few cases in his series treated with the tartrobismuthates and other bismuth compounds; Shivers likewise reports that in his series albuminuria did not occur but that on the contrary, several cases of presumably syphilitic albuminuria were greatly benefited by injections of bismuth. Blum[34] is of the opinion that albuminuria is only likely to develop in cases of stomatitis and that it may be due in part to the associated bacterial infection or be an expression of syphilitic irritation requiring a continuation rather than a cessation of treatment.

Rathery and Richard[35] report that large doses of sodium and potassium tartrobismuthate in oily suspension administered to dogs produced no marked lesions, even in cases where a nephritis had previously existed. However, cylindruria was aggravated in cases where it was present before the injections, showing that the kidneys were affected by the administration of bismuth. The urine and *renal function* of 16 patients undergoing tartrobismuthate treatment were also studied. In some patients a slight polyuria was noted, but this was far from constant and the previous condition of renal function did not seem to influence its appearance. When albuminuria was absent before the injections it did not appear thereafter. Two of the patients had a normal Ambard's quotient, and azotemia and phenolphthalein excretion before and after treatment. Of the other 14 cases who had definite signs of renal deficiency before treatment, 6 were slightly aggravated in this respect, 3 showed no changes and 5 were definitely improved. The favorable effects

observed in this last group were perhaps due to the fact that in those cases there were curable syphilitic lesions in the kidneys. The authors conclude that, while a deficient renal function does not contraindicate of themselves the administration of bismuth in syphilis, such treatment must be carefully supervised.

Kollert, Strasser and Rosner[36] observed slight albuminuria only rarely during the treatment of 39 syphilitics with trepol in dose of 0.2 to 0.3 grams at not less than 4 day intervals until 3.0 grams had been injected. On the other hand, in 27 cases an unusual sediment of small, polygonal finely granular epithelial cells was noted. In 4 cases a few erythrocytes were found but in none of the patients were there any symptoms of nephritis, such as edema. The authors also observed slight diuretic effects which were not however, as marked as after the administration of mercury, and they state that examinations of the urine for albumin alone may be insufficient for detecting irritation of the kidneys.

It would appear, therefore, that while large single doses of bismuth may produce renal irritation and stomatitis, multiple small doses at intervals of 3 to 7 days are not at all likely to produce these effects, since time is allowed for excretion before excessively large amounts accumulate in these organs. In my experience the intramuscular injection of a series of twelve to fifteen doses of 0.1 to 0.2 grams each of the tartrobismuthates at intervals of 5 to 7 days has rarely produced albuminuria or other signs of renal irritation and in several cases albuminuria following the injection of mercury has gradually disappeared under this kind of bismuth therapy. I believe, however, that it is well for the urine to be examined microscopically and for albumin routinely every two weeks at least during courses of bismuth injections and especially if there are evidences of gingival siderosis or stomatitis.

Provocative or Herxheimer Reaction after the Administration of Bismuth in Syphilis.—Klauder has observed that in syphilitic orchitis of rabbits the intramuscular injection of potassium tartrobismuthate in dose of 0.05 gram per kilogram was sometimes followed in forty-eight hours by increased swelling of the testicles and other signs of renewed spirochetic activity or the effects of toxic substances derived from the organism as a result of the injection.

These local reactions may be interpreted, therefore, as a provocative or Herxheimer reaction. In syphilitic human subjects I have occasionally observed the occurrence of pain and tenderness of enlarged lymph glands and tertiary skin lesions after one to three intramuscular injections of 0.2 gram each of potassium tartrobismuthate; also vague aches and pains in the heart muscle and other parts of the body, which may have been due to similar provocative effects. In some cases of latent tertiary syphilis the complement-fixation reactions have become stronger, and these effects are to be likewise interpreted as due to provocative stimulation or a serological Herxheimer reaction even though there were no clinical evidences of exacerbation of the disease.

Bismuth, therefore, may produce mild Herxheimer reactions in syphilis, that is, cause an exacerbation of the disease or of a particular lesion or lesions either by stimulating spirochetes into renewed activity or releasing from them by lysis toxic substances capable of exciting inflammatory reactions; these effects, however, are not nearly as common as after the intravenous injection of arsphenamn, neoarsphenamin or mercury because absorption is so much slower by intramuscular injection. Indeed, exacerbations of this kind are decidedly uncommon in the treatment of syphilis with intramuscular injections of 0.1 to 0.2 grams of potassium tartrobismuthate in oil and I do not

hesitate to administer these amounts even in neurosyphilis when the occurrence of a "neurorecidiv" reaction is to be feared and carefully avoided.

Local Reactions Produced by Intramuscular Injections of Bismuth.—The degree of local inflammatory reaction including pain produced by the intramuscular injection of bismuth varies considerably according to the nature of the compound and the vehicle employed. For example, sodium and potassium tartrobismuthate dissolved in water (luatol) is ordinarily so painful that a series of injections cannot be given, whereas when suspended in a vegetable oil (trepol) it is well tolerated and according to Klauder, suspensions of bismuth trioxid in olive oil are less painful than sodium and potassium tartrobismuthate in the same oil.

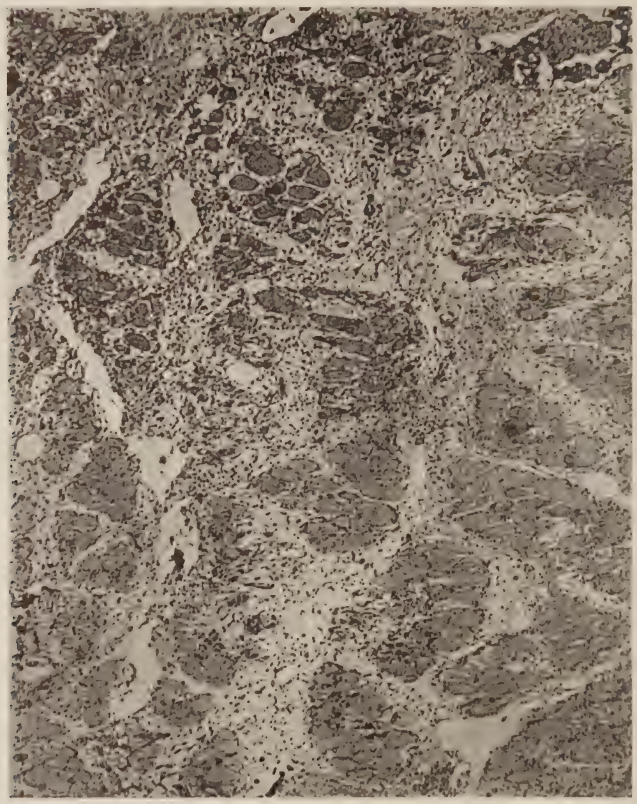

FIG. 30.—LOCAL REACTION PRODUCED BY THE INTRAMUSCULAR INJECTION OF BISMUTH IN OIL.

Injection of 0.025 gm. of potassium tartrobismuthate in 0.5 c.c. of almond oil (six days).

On the other hand, the degree of pain and discomfort following the intramuscular injection of any preparation varies considerably among different individuals even when extraordinary precautions are taken to inject each with the same dose and in exactly the same manner; furthermore, among individuals receiving a series of injections, the pain and discomfort varies even though the same dose is given, although not exactly at the same site. In the majority of instances the intramuscular injection of 0.2 grams of potassium tartrobismuthate suspended in 2 c.c. of sterile olive oil with the addition of 10 minims of a 2 per cent. solution of butyn, has produced no

immediate discomfort, but an area of tenderness and some pain at night when lying in bed, and disturbance of sleep. The injected area is ordinarily slightly tender for several days but may prove so annoying in nervous "high strung" patients as to constitute an obstacle to repeated injections. On the other hand this preparation produces somewhat less pain and discomfort and is better borne than grey oil, suspensions of salicylate of mercury or calomel in oil.

Histological studies of muscles excised about five days after injections of the tartrobismuthates in rats have shown that these salts produce varying degrees of necrosis of those muscle cells in direct contact with the deposited drugs accompanied by well marked degrees of leukocytic infiltration. The effects produced by potassium tartrobismuthate, sodium tartrobismuthate and the quartenary salt of sodium and potassium tartrobismuthate are quite similar in kind and degree, but the reactions produced by solutions of these in sterile water are almost always more severe than similar doses in sterile almond oil (Fig. 30). The water solutions produce a smaller, but more intense reaction which may progress to the stage of liquefaction necrosis; the oily suspensions produce a more diffuse reaction in which there is less necrosis of muscle but in which the neighboring muscle is more broadly infiltrated with polymorphonuclear leukocytes.

Why the same preparation administered in exactly the same dose, and at least approximately if not exactly in the same area, should excite a greater degree of local reaction in some individuals than in the majority, is not known; however, the reactivity of the skin of different persons to intradermal injections of various substances is known to vary in that pustular reactions may develop in some and almost no reaction at all in others injected with the same substance in the same dose and in the same manner. Individuals taking the iodids are especially likely to develop pustular reactions following intradermal injections and I believe that the same mechanism may influence the reactions following intramuscular injections. In other words the kind and degree of inflammatory reaction that may be excited in the muscles varies, not only according to the direct irritating properties of the medicament injected but also according to the degree of sensitiveness of the individual to any irritant; for this reason some individuals react excessively with dense collections of leukocytes and the tendency for pus production, while others react scarcely at all so that the matter of pain following intramuscular injections is not altogether a matter of a general "high strung" or nervous disposition and intolerance for pain.

In this connection, it is interesting to note that intramuscular injections of the tartrobismuthates to rats, after the daily administration of potassium iodid by stomach tube for five days, have frequently produced more severe local histological changes than in control rats receiving only the intramuscular injections. In the iodid rats the local lesions were larger and more pustular. However, this influence of potassium iodid is not demonstrable clinically; I have many times given a series of intramuscular injections of potassium tartrobismuthate in dose of 0.2 grams in 2 c.c. of sterile almond oil every five days while patients were taking internally from 15 to 60 grams of potassium iodid daily without noting that the local reactions were in any manner larger or more painful than in cases to whom the iodids were not being administered.

As previously stated, water solutions of the tartrobismuthates are more painful and produce more severe histological changes than suspensions in sterile almond or olive oils. This is readily understood, because the oil is bland and soothing and prevents the sudden contact of the bismuth compound with the tissues; furthermore, absorption of the oil is delayed since

soaps are produced by contact of the vegetable oil with the alkaline tissue juices. Mineral oils, as paraffin oil, do not saponify and greatly reduce the rapidity of absorption without, however, appreciably reducing the pain or tenderness.

Nodules in the tissues following intramuscular injections are purely a matter of inflammatory reactions and rapidity of absorption of drug and exudates. In my experience the tartrobismuthates in dose of 0.1 to 0.2 grams suspended in 1 to 2 c.c. of sterile olive or almond oils produce less nodulation than when dissolved in 1 to 2 c.c. of water or suspended in 1 to 2 c.c. of sterile paraffin oil.

In any event the addition of phenol and a local anesthetic as butyn or anesthesin to either watery solutions or oily suspensions of the tartrobismuthates greatly reduces the immediate pain and discomfort of injections and should not be omitted; the formulas proving especially useful are given in Chapter LXIV.

Mechanism of the Toxicological Action of Bismuth in the Treatment of Syphilis.—The toxicity of the various organic and inorganic compounds of bismuth advocated and employed in the treatment of syphilis apparently depends upon the dissociated ions of bismuth itself in just the same manner as the toxicity of the mercurial compounds depends upon the dissociated ions of mercury. When the soluble salts are injected intravenously, toxic effects may be due to immediate or almost immediate intravascular changes similar to the immediate reactions sometimes following the intravenous injection of the organic arsenical compounds and particularly arsphenamin; when injected intramuscularly, these immediate reactions are not likely to occur as absorption is so slow that the intravascular reactions do not result or are of a minor grade and without symptoms.

In general terms it would appear that the toxicity of various bismuth preparations bears a relation to the amount of bismuth contained and this would be true if the compounds were equally soluble in the tissue fluids and if the bismuth ions were dissociated with equal rapidity from the different compounds. While the toxicity of the organic and inorganic mercury compounds bears a relation to the amount of mercury contained in each yet toxicity has an even closer relation to the degree of solubility of the compounds and more particularly to the degree of dissociation of the mercury ions; for example, a full complex compound may contain more mercury than a half or pseudocomplex compound and yet prove less toxic (and likewise less therapeutic) than the latter because the mercury is so firmly bound that the compound may be absorbed and eliminated in large part unchanged. I believe that exactly the same principles govern the toxicity of bismuth compounds for both the host (organotropism) and the parasites (parasitropism).

The toxicological action of bismuth is similar to that of mercury in other respects as well. For example bismuth acts upon the epithelium of the uriniferous tubules of the kidneys in exactly the same manner producing albuminous degeneration and final liquefaction necrosis; the deposition of calcium in the degenerated cells likewise occurs as in mercurial intoxication but not as extensively. Similar effects are produced in the liver, in the muscles at the site of injection and other organs; the degree of reaction in all organs is, however, less than occurs with mercury so that it appears that the toxicity of bismuth ions is less for the body cells than mercury ions although at least five times more toxic for *Spirochæta pallida* than the latter.

Toxicity of bismuth, of course, bears a relation to the condition of the eliminative organs. This is seen particularly well in the mouth since individuals with Rigg's disease or gingivitis (pyorrhea alveolaris) are cer-

tainly more prone to siderosis and stomatitis than those whose gums are sound and healthy. Such individuals may show no signs of toxicity elsewhere although albuminuria is more likely to develop if stomatitis is present. Apparently the buccal mucosa, kidneys and intestinal mucosa are able to eliminate promptly and without apparent injury the bismuth dissociated from 2 to 3 grams of the tartrobismuthates given intramuscularly in doses of 0.1 to 0.2 gram over 10 to 12 weeks of time, provided these organs are sound and healthy; if these tissues are inflammed, however, and particularly the gums, the bismuth is precipitated at the points of elimination and converted into solid particles producing siderosis (blue line) and ultimately ulceration, if the bismuth accumulates in the tissues and capillary walls to a sufficient degree to occlude the vessels.

The mechanism of production of siderosis, stomatitis and allied lesions is, therefore, fairly well established, but it is more difficult to explain the mechanism of the bone and muscle pains, particularly of the legs, thoracic pains and the skin lesions. It is probable that the former are due to neuritis in a manner analogous to arsenical and mercurial neuritis; the latter may be due to irritation produced by the elimination of bismuth through the excretory channels of the skin, to a state of hypersensitiveness to bismuth or the result of bacterial anaphylaxis from foci of infection activated by the depressive and toxic effects of the drug.

Mechanism of Toxic Reactions Following Intravenous Injections.—Just why the water soluble tartrobismuthates and other soluble compounds of bismuth injected intravenously should prove so toxic as to render unsafe and unwise this route of administration is not clear. Mercury for example, is certainly more toxic than bismuth by intravenous as well as intramuscular routes of administration since the maximum tolerated dose of the bichlorid is about 0.006 gram per kilo while the soluble tartrobismuthates are tolerated in doses of 0.020 to 0.030 gram per kilo. Furthermore, the bichlorid and other soluble compounds of mercury can be given intravenously with safety if well diluted and slowly injected although repeated injections may produce plebitis is some instances. I believe that the dangers of intravenous injections of the tartrobismuthates have been overemphasized by Levaditi and others although there does not appear to be any important reason why the intravenous route is the one of choice since absorption is so prompt from the muscles, unless it is for the treatment of acute syphilis when the organic arsenical compounds as arsphenamin or neoarsphenamin cannot be given because of hypersensitiveness.

The symptoms produced as dyspnea, cough, thoracic oppression, etc., and some of the lesions found in the lower animals as emboli of agglutinated erythrocytes in the capillaries of the lungs, liver and kidneys, folllowing the intravenous injection of large amounts of the tartrobismuthates, suggest that bismuth may produce masses of precipitated plasma proteins and agglutinated erythrocytes when injected intravenously in much the same manner as these may be produced by arsphenamin. My experiments have shown that sodium tartrobismuthate and potassium tartrobismuthate may agglutinate *washed* human erythrocytes in final dilutions as high as 1:30,000 to 1:50,000 in an exposure of one hour although hemolysis is produced only in final dilutions of 1:100 to 1:200. Similar results were observed with washed sheep corpuscles, but when the tests were conducted with *unwashed* human and sheep blood it was found that agglutination and hemolysis did not occur even with final dilutions as low as 1:200. In other words, the presence of serum protects erythrocytes against agglutination and hemolysis by bismuth *in vitro* just as serum protects erythrocytes against agglutination and hemolysis

in vitro by arsphenamin and mercury, as described in preceding chapters. These results, of course, greatly reduce the significance to be attached to the agglutinating and hemolyzing properties of bismuth as factors responsible for immediate reactions when the soluble salts are injected intravenously. Furthermore, sodium tartrobismuthate and potassium tartrobismuthate added to serum *in vitro* produce insoluble albuminates much more slowly than mercuric chlorid, and I doubt if precipitation of plasma proteins occurs to sufficient extent intravascularly to be of primary importance from the toxicological standpoint.

Doubtless, however, intravenous injection of the soluble tartrobismuthates and other compounds of bismuth may produce the same kind of obscure colloidal and other changes in the plasma as may follow the intravenous injection of arsphenamin and mercury and it is barely possible that these effects are due primarily to alkali and other substances aside from the bismuth itself, but the exact mechanism of these immediate reactions is just as obscure as is true of the early or immediate arsphenamin reactions and I believe that they could be avoided or greatly minimized by the same precautions observed in the administration of arsphenamin, namely, to inject the compound slowly and after being well diluted with saline solution.

Prophylaxis of Toxic Reactions by Bismuth.—All that has been written in Chapter LIII regarding the prophylaxis of toxic reactions by mercury applies equally well to bismuth. Special attention should be given the condition of the teeth and gums and throughout the administration of bismuth the patient should be carefully instructed, if necessary, regarding the proper cleansing of the teeth and gums and the hygiene of the mouth. Precautions of this kind go far in preventing stomatitis, although the danger of its production is not as great as when mercury is administered.

Constipation and dietary errors should be corrected as likewise other gastro-intestinal disorders as may be amenable to improvement or removal.

Renal irritation and albuminuria do not necessarily contraindicate the administration of bismuth, but it is well to carefully examine the urine once every 2 weeks at least to detect or guard against the production of bismuth injury of these organs.

If a soluble salt is administered by intravenous injection, the dose should be well diluted and slowly injected to prevent or minimize the colloidal shock reaction that may follow. When intramuscular injections are given, due precautions should be taken against accidental intravenous injection.

Local reactions are minimized by giving them strictly intramuscularly or epifascially as described in Chapter LXIV; subcutaneous injections are apt to be more painful and result in nodosities. The immediate pain is well controlled by incorporating an anesthetic.

Treatment of Bismuth Toxic Reactions in Syphilis.—Insofar as bismuth poisoning is concerned in relation to its administration in the treatment of syphilis, only stomatitis requires much consideration.

For the acute early reactions that may follow intravenous and rarely intramuscular injections, symptomatic treatment only may be given, as there is nothing in the form of specific medication since so little is known of the exact mechanism of these reactions. Acute bismuth poisoning due to over dose is not likely to occur since bismuth is injected by the physician and the opportunities for error on the part of the patient are not nearly as great as in the case of mercury when toxic amounts may be swallowed. In case of acute poisoning due to the accidental administration of an excessive dose, I believe that the most dangerous lesion would be acute tubular nephritis with symptoms similar to acute bichlorid of mercury poisoning and requiring exactly

the same kind of treatment including the intravenous injection of sodium thiosulphate.

As a general rule, the vague muscular pains, malaise and anorexia following the first few doses disappear as treatment is continued; if, however, these symptoms persist with increasing anemia, loss of weight and with the appearance of siderosis of the gums, the dose injected should be reduced or the administration stopped.

When bismuth is administered, the gums should be examined at every visit of the patient and it is well not to begin the injections if severe gingivitis is present until the gums have received appropriate preliminary treatment and especially removal of tartar deposits with some degree of healing as well as the extraction of decayed roots and the filling of carious teeth.

The appearance of a slight blue line about the incisor teeth does not necessarily mean that treatment must cease if the gums are otherwise healthy. It is my practice to routinely inject 0.2 gram of potassium tartrobismuthate intramuscularly every 5 days and to reduce to 0.1 gram as the dose upon the first appearance of siderosis. Under these conditions a full course amounting to a total of about 2 grams can usually be given in 8 to 12 weeks.

If stomatitis develops and particularly if ulceration occurs with halitosis, the injections should cease at once and appropriate treatment applied to the gums. Bacteriological examination usually discloses the presence of enormous numbers of spirochetes with numerous fusiform bacilli and when such is the case, I believe that local applications of arsphenamin or neoarsphenamin yield best results, as described in Chapter XXXI. Palazzi[37] states that the local application of a 100 per cent. solution of methylene blue is efficacious and that arsphenamin or neoarsphneamin injected intravenously has an undoubted curative influence upon these spirochetic infections. Potassium chlorate mouth washes are also helpful.

CHAPTER LVI

PHARMACOLOGY OF THE IODIDS IN RELATION TO THE TREATMENT OF SYPHILIS AND OTHER DISEASES

Since 1836, when potassium iodid was first advocated by Wallace, of Dublin, for the treatment of syphilis, this remedy has remained an almost undisputed agent in the therapeutics of this disease and especially for the treatment of the tertiary lesions, as so early shown and emphasized by Ricord. Even to this day, however, the exact mechanism of its wonderful curative effects is not definitely known, and we can only state that evidence shows that, in the amounts ordinarily administered, it possesses but feeble spirocheticidal effects. But the wonderful manner with which it brings about the absorption of inflammatory exudates and fibrous tissue, not only in syphilis but in other infections as actimomycosis, sporotrichosis, tuberculosis, etc., renders the iodids of great interest and importance in the chemotherapy of these infections, as I shall discuss shortly with more detail.

Chemistry of the Iodids in Relation to the Treatment of Disease.—Naturally, with a remedy so valuable, a very large number of new inorganic and organic compounds of iodin and iodid have been described and advocated for the treatment of syphilis and other diseases. But we are not at all interested in the iodin compounds, insofar as the chemotherapy of syphilis and other infections are concerned, because it is well established that in these it is the iodid ion and not the iodin ion that is of importance. The inorganic iodids, however, like potassium iodid and sodium iodid are rapidly eliminated and numerous attempts have been made to produce organic compounds of slower dissociation and elimination of the iodid ion. For this purpose a very large number of iodo-albuminates, -peptonates, -tannates, etc., have been prepared, but, as shown by McLean[1] and others, these are so rapidly decomposed that they behave and are excreted practically like the inorganic iodids and have no advantage over either sodium or potassium iodid. However, combinations of iodids with oil (*iodipin*) and fatty acids (*sajodin*), as well as *iodostarin* and *lipoiodin*, are absorbed, decomposed and excreted more slowly. McLean found that they are largely retained in the lipoid-soluble fraction of the cells and, therefore, likely to penetrate the nervous system more freely than the inorganic iodids; Jacoby,[2] however, states that iodin is not stored in tissue fat when iodized fatty acids are administered as such by ingestion, but only when given in the form of their calcium salt.

But for all practical purposes, potassium iodid and sodium iodid are quite satisfactory for the treatment of disease, although a good working knowledge of their absorption, distribution and retention in the tissues, and especially their elimination, is required in order that they may be properly administered in such manner as may maintain the maximum curative concentration in the tissues and fluids for sufficient periods of time. Attempts to reduce the toxicity of the iodids are praiseworthy, but hardly worth while, since both salts and particularly sodium iodid are of remarkable low toxicity for both human beings and the lower animals, although some individuals possess a marked hypersensitiveness to the iodid ion, regardless of the chemical nature, organic or inorganic, of the compound by which it is introduced into the body.

Iodid compounds of mercury, lead, etc., have not proved useful from the standpoint of iodid therapy, because the high toxicity of the metal prevents the administration of sufficient amounts to give well-defined iodid effects. But if the iodid ion could be introduced into the arsphenamin or neoarsphenamin molecule without greatly increasing toxicity, I believe that a distinct achievement and advance in the chemotherapy of syphilis, especially in its tertiary stages, would result. And if success attends present and future efforts to evolve a chemotherapy for tuberculosis, actinomycosis, sporotrichosis, etc., I believe that the introduction of an iodid ion will greatly aid in localizing the parasiticidal agent of the compound in the diseased tissues and aid in opening paths of access to the infectious agents.

For all practical purposes the two inorganic salts, potassium iodid and sodium iodid fulfill the requirements for the treatment of infectious diseases; iodin or compounds liberating free iodin are of no particular interest in the treatment of syphilis, actinomycosis, sporotrichosis, etc.

Of these two salts, sodium iodid is much less toxic than potassium iodid—at least six or seven times less toxic, as will be shortly described—and is to be preferred to potassium iodid for intravenous injection. The difference in toxicity is due to the dissociation and higher toxicity of potassium and the more rapid excretion of sodium iodid; the iodid ion appears to be of the same toxicity in both. Ammonium iodid is said to be more liable to produce the skin eruptions and gastrointestinal disturbances. Occasionally these iodids cannot be administered by ingestion in adequate doses to some patients by reason of gastric and other disturbances; in these I have sometimes found pepto-iodin, prepared by Raiziss, better borne, as likewise, lipoiodin and other organic compounds.

Absorption of the Iodids in Relation to Methods of Administration.—The iodids are rapidly absorbed from mucous membranes, so that, with oral administration, the absorption occurs principally from the stomach, the peak of highest concentration of iodid and iodin in the blood being reached about one hour after the ingestion of 15 to 45 grains and about two hours after the ingestion of 300 grains. Absorption through the skin, however, is so slight as to be therapeutically worthless. Absorption also occurs from the intestine including the rectum.

Fournier states that, in 1867, examinations of the urine from a case of ectopic bladder with the ureters opening about three inches above the pubis, so that the urine could be collected from the moment when it first began to drop, showed the presence of iodid after the following intervals:

After ingestion by the stomach	14 or 15 minutes.
After placing on the tongue	14½ minutes.
After subcutaneous injection	20½ minutes.
After injection into the rectum	23 minutes.

Hanzlik,[3] in 1912, found that the absorption of sodium iodid solutions placed in ligated loops of small intestine, was nearly equal in all parts; absorption from the stomach and colon was somewhat less. The rapidity of absorption was not materially influenced by the extent of surface, or by the concentration of the solution. The absorption was very rapid at first, but slower after absorption of the first one-half to three-quarters of the amount injected due to local changes in the epithelium. Sodium iodid is probably absorbed somewhat more rapidly than potassium iodid; at least it is excreted more rapidly, as will be shortly discussed.

It is sometimes recommended to administer the iodids by ingestion with fats in the form of milk and cream on the theory that the lipoids hasten absorption. The observations of Osborne,[4] however, have not substantiated these claims, as he observed no difference in the rate of absorption of potassium and sodium iodids due to fats in ordinary meals, as compared with the empty stomach. *Patients noted less gastric irritation when the drugs were taken on an empty stomach one-half hour before meals.* Sodium iodid was better tolerated, both by ingestion and intravenous injection, than potassium iodid.

Within recent years sodium iodid has been recommended for intravenous injection, but, owing to the rapid absorption from the stomach and intestines, this route does not appear to be indicated except in exceptional cases of syphilis, sporotrichosis, etc., when sufficient amounts cannot be given by ingestion owing to gastro-intestinal disturbances or when a very high concentration in the blood for a short time is required for extra rapid effects. Osborne, for example, has found that, after the intravenous injection of 10 gm. of either sodium or potassium iodid to adults, the iodin content was 0.043 gm. for 100 c.c. of blood serum at the end of one hour, 0.0247 gm. at the end of four hours, 0.0071 at the end of twenty-four hours and only a trace by the end of the fourth day. However, the oral administration of 3 to 5 gm. (45 to 75 grains) three times a day is equal to a single dose of 10 gm. (150 grains) intravenously, and has the added advantage of producing a uniformly sustained concentration of iodid and iodin during the day. The giving of large doses by vein produces a very much higher concentration for a much shorter period. Oral administration creates a moderate but prolonged concentration in the blood and tissues; intravenous administration of large doses creates peaks of high concentration followed by rapid declines.

It would appear, therefore, that, for routine treatment, the iodids should be administered by ingestion and intravenous injections employed only in exceptional cases. As stated by Osborne, it seems that unless intravenous injections are used as adjuncts to oral administration, there is no special advantage in giving small doses intravenously. In the treatment of neurosyphilis, however, intravenous injections of 10 to 20 gms. of sodium iodid (100 to 200 c.c. of 10 per cent. solutions) may be advantageous, since these are followed by a marked increase of iodid in the cerebrospinal fluid and possibly also in the syphilized portions of the brain and cord, much higher than can be secured by oral or rectal administrations, as shown by Osborne and to which further reference will be shortly made.

In exceptional cases of gastric intolerance, the iodids may be administered by rectum, at least for a period of a week or two at a time. Absorption is quite rapid; according to some pharmacologists, better than from the stomach, and it is possible to administer solutions by this route. According to my experience suppositories are less well borne, apparently because of irritation due to concentration of the drug. Osborne has observed, however, that when 3 to 10 gms. of potassium iodid were given two patients by drop

proctoclysis per day, only 16.9 to 43.3 per cent. of the iodin was excreted in the urine. Increasing the dose above 10 gm. daily did not produce a corresponding increase in absorption and in both cases, severe rectal irritation developed when the dose reached 30 gm. of potassium iodid daily. According to these results, it appears that approximately only 20 to 25 per cent. of iodid given by rectum is absorbed; since 96+ per cent. is absorbed after oral administration, a daily dose of 2 to 3 gm. (30 to 45 grains) by mouth is equivalent to 10 gm. (150 grains) by rectum. Therefore, it would seem that the rectal administration of iodids offers no particular advantage in the treatment of disease.

Mechanism of Absorption and Circulation of Iodids.—The iodids being freely soluble are doubtless absorbed directly into the lymph and venous blood through the epithelium of the glands of mucous membranes. The studies of Osborne have suggested, however, that after absorption of potassium iodid an exchange of ions occurs in that the potassium is replaced by sodium to a large extent. For example, after the ingestion of 1, 5 and 20 gms. of sodium iodid, Osborne found that a definite rise in the sodium content of the blood proportional to the size of the dose; but after the ingestion of similar amounts of potassium iodid, no such change in the potassium content of the blood occurred except a slight increase after the 20 gm. dose. On the contrary, a rise in the sodium of the blood was observed. After intravenous injections of 10 gm. of sodium iodid, the sodium content of the blood remained high for twelve hours, and returned almost to normal at the end of forty-eight hours. After the injection of the same amount of potassium iodid, however, no such increase in potassium occurred. Osborne then observed after the ingestion of sodium iodid, that only traces of iodin were found in the serum protein, while after intravenous injections from 6 to 9.9 per cent. of the iodin was found in these proteins. After the ingestion of potassium iodid, however, an average of 16.8 per cent. of iodin was found in the serum proteins. Analyses of the blood serum lipoids showed only traces of iodin in the alcohol- ether- and chloroform-soluble fractions after potassium and sodium iodid by mouth and sodium iodid intravenously.

The significance of these observations in relation to the toxicity of the iodids must yet be determined, but it would appear that, after the administration of sodium iodid, the whole molecule is absorbed without dissociation of the sodium or union with the proteins, whereas after the administration of potassium iodid, the potassium is absorbed only to a slight degree while the iodid ions unite with the serum proteins to form a sodium protein combination. Possibly changes of this sort may account in part for the higher toxicity of potassium iodid and such effects as higher hemolytic activity. After absorption of the iodids, the large portion circulates in ionic form, passes through the tissues in this form and is largely excreted in the urine in the form of salts. However, a small amount evidently undergoes decomposition into free iodin, since some may be found in the stomach and an increase sometimes occurs in the thyroid gland after the administration of potassium iodid. Furthermore, an organic compound of iodin is known to occur in the hair and in various internal organs particularly the liver, after iodid therapy. However, free iodin thus liberated does not circulate as such, but in combination with the plasma proteins, as above stated; insofar as the treatment of syphilis and other infections is concerned, only the iodid ion and not either free iodin or organic protein-iodin compounds are of particular interest.

Elimination of Iodids in Relation to Methods of Administration.—Iodids are mostly eliminated in the urine, with traces in the saliva, tears, perspiration, milk, sebum, nasal discharges and gastric juice; in the latter, they occur

as hydriodic acid, from which free iodin may be liberated. Only very small amounts are eliminated in the feces. Osborne found that, following a dose of 5 gm. of sodium iodid, 0.2 gm. of iodin was found in the feces, and after a dose of 20 gm. of potassium iodid, 0.250 gm. of iodin appeared in the feces. Thus, 96 per cent. was absorbed from the gastro-intestinal tract, and this in spite of the fact that 20 gm. doses produced a mild watery diarrhea in some of his cases. About 1 per cent. of iodid is eliminated in the bile in twenty-four hours, the maximum in the first three hours, but apparently re-absorption occurs to some extent in the lower intestine. Elimination also occurs in other fluids, as transudates and inflammatory exudates; of special interest, from the standpoint of the treatment of neurosyphilis, is the occurrence of iodid in the cerebrospinal fluid.

In the urine the iodids are eliminated largely as iodid ions; a part is also apparently eliminated as salts and in organic combinations, but the evidence of the latter is somewhat controversial and unconvincing. They appear in the urine in ten to twenty minutes after ingestion and reach a maximum in from two to four hours; no appreciable differences are noted in the rates of elimination when the drugs are given before or after ordinary meals. About four-fifths is excreted within a few hours and the balance, except for traces, by the end of ninety-six hours regardless of the dose. The amount of urine excreted does not materially influence the iodin output.

Salivary excretion begins usually in six to eleven minutes, being somewhat delayed when taken on a full stomach. A metallic taste is imparted to the saliva, best corrected by gargling with bicarbonate of soda, but there is rarely an odor of the breath, although patients and particularly women, sometimes object to iodid therapy because of a suspicion of halitosis.

Elimination in the milk, known to Fournier, and studied with particular care by Reipt and Scheffer,[5] is of particular interest in the treatment of syphilis of infants, since it is possible to administer the drug to them by this route through their mothers or wet nurses in much the same manner as mercury or arsphenamin and its substitutes.

According to Osborne, sodium iodid is excreted faster during the first hour than potassium iodid. The percentages for the one-hour interval following the administration of 1 gm. of sodium iodid and 1 gm. of potassium iodid, respectively, were 5.3 and 2.2; 7.3 and 7.2 after 5 gm., and 10.9 and 2.0 after 20 gm. Other pharmacologists, however, found that the cathions had no influence upon rapidity of elimination, and that sodium, potassium and ammonium iodids are excreted precisely alike, both in regard to rate and total quantity. The administration of related ions, like chlorids and bromids, however, apparently exert an influence, since some pharmacologists have found that chlorids and related ions hasten elimination while foods poor in chlorin increase retention. However, the excretion of iodin after the ingestion of the iodids is about the same for all compounds, although Osborne observed that the percentages were on the average a trifle higher with sodium iodid. Of particular interest in relation to methods of administration is the comparative rates of elimination after intravenous and oral administrations; I may quote Osborne in this connection, who states on the basis of a study of results following doses of 5, 10 and 20 gm. of sodium iodid: "(1) There is no striking difference in the rate of elimination of sodium iodid given intravenously, as compared with that given by mouth. Mendel has contended that sodium iodid administered intravenously is retained in the body for a longer period. My observations indicate that there is practically no difference between the two methods in the rate of elimination, and large doses are eliminated as rapidly as small ones.

"(2) There is a rapid adjustment of the body fluids to the hypertonic sodium iodid solution (10 per cent.). After 5 gm. of sodium iodid intravenously, the concentration of iodin in the urine rises immediately; while, after the 10 gm. dose, it is a trifle slower. With the relatively large dose of 20 gm., the urinary concentration remains comparatively low until the end of the first hour, after which it rapidly rises to a maximum during the fourth hour. Clinical experience coincides with these findings. Practically every adult patient tolerates 10 gm. of sodium iodid intravenously (100 c.c. of 10-per cent. solution) very well because the body is able to adjust itself to that amount. Above 10 gm., symptoms may develop from the effect of the hypertonic solution. No accumulation of the drug in the body after the large daily doses intravenously occurs. On 30 to 45 gm. daily, the same percentages were obtained as with small doses, and the drug did not remain in the body any longer."

Retention and Distribution of the Iodids in Relation to the Treatment of Syphilis and Other Diseases.—As previously stated, only a small part of the iodids administered are retained; fully 65 to 80 per cent. appears in the urine within twenty-four hours after their administration, and no iodid reaction is obtained from any of the secretions a week after treatment has ceased. The fate of the retained iodid is not, however, clearly established. In the first place the amounts retained varies with different individuals; thus as stated by Cushing, one patient receiving 0.5 gm. of potassium iodid may retain 0.1 gm., while another after the same dose may retain 0.2 gm. or more, the same proportions appearing on different occasions.

The largest amounts are apparently retained in the thyroid gland followed in order by the blood, secretory and lymph glands, kidneys, lungs, muscles, intestines, testes and bones. Only traces occur in the hair and none in the brain, spinal cord or bone marrow (except traces if the lipoid-soluble organic forms are given). Recently Steiglitz,[6] who worked out a histological method for studying the distribution of iodids, found them chiefly in the secreting cells of parenchymatous organs such as the liver and kidneys; also in the epithelium of the mucosa of the trachea and bronchi. McLean found after the administration of potassium iodid and iodalbin, that 68 per cent. of the iodin was present in the water soluble fraction of the liver, 32 per cent. in the lipoid, and none in the protein. After the administration of sajodin (iodized fat), however, 58 per cent. was found in the lipoid fraction and 42 per cent. in the water-soluble fraction.

Of special interest in the distribution of the iodids are their presence in the cerebrospinal fluid and inflammatory exudates, especially the exudates and gummas of syphilis. Catton,[7] in a study of the spinal fluid of four patients who had taken 15 grains of potassium iodid three times a day for periods varying from seventeen days to three months, found none in the spinal fluids. Mehrtens[8] found that spinal fluid drawn one hour after the last of four intravenous injections every half-hour of 50 grains of sodium iodid contained no iodin, but cases previously treated with an intraspinal injection of 10 c.c. of sterile horse serum showed traces of iodin, presumably due to an increased permeability of the choroid flexus and vascular changes of the meninges as the result of irritation by the horse serum. A very comprehensive study by Osborne,[9] however, has shown that iodin (determined by Kendall's method) is found in normal spinal fluid (0.000019 to 0.000024 gm. per 100 c.c.) and undergoes an increase after the administration of iodids by various methods. After the ingestion of potassium iodid in dose of 50 to 100 grains three times a day, spinal fluids drawn two to seventy-two hours after the last dose showed from traces to 0.00037 gm. per 100 c.c. After the rectal injection of 125 to 200 grains of potassium iodid by rectum three times a day, spinal fluid drawn one to twelve hours after the last dose showed 0.000381 to 0.0018 gm. per 100 c.c. After the intravenous injection of 10 to 20 gm. of sodium iodid in 10-per cent. solution to normal individuals, spinal fluid drawn fifteen minutes to forty-eight hours later showed amounts of iodin varying from 0.0027 gm. (two-hour interval) to 0.0003 gm. (twenty-four-hour interval) per 100 c.c. of fluid. In a series of three cases of

neurosyphilis given daily intravenous injections of 10 to 40 gm. of sodium iodid for two weeks with spinal puncture half to twenty-four hours after the last dose, as much as 0.0048 to 0.0423 gm. of iodin per 100 c.c. of fluid were found. In one case of neurosyphilis receiving one intravenous injection of 20 gms. of sodium iodid, as much as 0.00437 gm. of iodin per 100 c.c. of spinal fluid was found two hours later. Osborne concluded that iodin in increased amounts is present in cerebrospinal fluid following the administration of iodids by mouth, by rectum and intravenously and especially after the last route of administration. His work also suggests that neurosyphilitic tissues take up more iodin than normal tissue and that the presence of syphilitic meningitis increases the permeability of the choroid plexus and meninges to iodin compounds in the blood.

Loeb[10] had previously shown that syphilitic lymph glands retain more iodid than normal tissues, and this increased retention of iodids by syphilitic tissues is a matter of considerable significance from the standpoint of chemotherapy, since it probably opens up a means for bringing spirocheticidal agents in contact with the parasites. Of equal importance are the studies showing that tuberculous tissues and particularly the necrotic portions, contain increased amounts of iodids since advantage may be possibly taken of this to effect some combination between iodid and tuberculocidal drugs and thereby favor the more direct access of the latter to the tubercle bacilli. Carcinomata and various granulomata as in actinomycosis, sporotrichosis and other necrotic tissues likewise show an increased retention of iodids. Just how or why this affinity exists between iodids and the inflammatory exudates of syphilis, tuberculosis, actinomycosis, etc., cannot be stated. Evidently there is nothing specific about the process, since increased amounts of iodids are to be found in the necrotic tissues produced by various bacteria and indeed, by sterile chemical irritation; evidently it is a matter largely of simple diffusion in which dying and dead cells no longer offer resistance to the diffusion of the salts. Apparently the iodin exists in syphilitic and tuberculous tissues as organic compounds of lipins rather than of proteins, as shown by Fujisawa;[11] in pus, however, and exudates generally, the iodin has been found as inorganic iodids.

Influence of Iodids upon Pathological Tissues and Secretions and the Mechanism of Their Therapeutic Activity.—This naturally raises the question what effect the increased retention of iodids may have on pathological tissues and exudates and the course of subsequent events. The chief effect is one of softening and liquefaction of the diseased tissues and secretions. The results of iodid therapy in tertiary syphilis are sometimes little short of marvelous, insofar as the rapid disappearance of gummas is concerned. This does not mean that the spirochetes are necessarily killed by the iodids; indeed, available evidence indicates that the iodids are very feeble spirocheticidal agents, as reviewed in Chapter XXVI, but I am not so sure but that the products of protein digestion, in the nature of the products of liquefaction necrosis, are sufficiently spirocheticidal, as they are known to be bactericidal, to possibly sterilize gummas. At least, they facilitate the access of such spirocheticidal agents as the oxids of arsphenamin and its substitutes, mercury and bismuth, if they happen to be present in the body. For this reason I believe that large doses of the iodids in syphilis should always be preceded and accompanied by the administration of arsphenamin, neoarsphenamin or one of their substitutes, mercury or bismuth, to secure the maximum therapeutic results and to prevent the possible dissemination of living spirochetes; doubtless, if we had tuberculocidal and leprocidal agents of equal potency, the administration of the iodids would be much less dangerous in tuberculosis and leprosy.

Likewise, in tuberculosis, leprosy, actinomycosis, sporotrichosis, blastomycosis, etc., there is usually observed a breaking down of the granulomatous tissues with liquefaction of the exudates and secretions; indeed, for this reason, the iodids are usually contraindicated in tuberculosis and leprosy, because of the danger of disseminating the bacilli, since no means are available for bringing about their simultaneous destruction such as we possess in syphilis. Bronchial secretions are likewise liquefied, and for this reason the iodids are frequently useful in the treatment of bronchitis and bronchiectasis, with or without asthma, and especially when the secretions are very heavy, viscous and difficult to "get under" for expectoration.

How do the iodids produce these results? Why do they not act in a similar manner upon normal tissues? The second question is probably more difficult to answer than the first, but it is apparently due to the fact that tissues devitalized by spirochetic, bacterial or sterile chemical agents (as intracutaneous injections of agar, luetin, etc.) absorb more iodid than normal tissues and that the difference is largely one of quantitative variations. For my own part, I believe that the answer to the first question is to be ascribed to the effects of an increase of proteolytic activity in the pathological tissues, secretions and exudates, as explained by Jobling, Petersen and Eggstein,[12] along possibly, with an actual increase of proteolytic ferments, as suggested by Dick. Certainly the older theories of liberation of free iodin (Binz), increased leukocytosis, phagocytosis and capillary permeability (Heinz), salt action and effect upon the thyroid gland, etc., are entirely obsolete or too general and indefinite to explain these specific effects of the iodids. According to Jobling and his colleagues, the proteolytic ferments of cells are held in physiological check or equilibrium by the unsaturated carbon atoms of the lipoids of the plasma constituting the antiferment or antitrypsin of the body fluids. The administration of the iodids and other halogens as well is followed by the saturation of these carbon groups, which thereby removes or reduces antitryptic activity, followed by increased proteolysis by the proteolytic ferments normally present in all cells as well as in the blood plasma and other tissue juices. This increased proteolytic activity results in a digestion of the dead protein material and of such cells as are so far devitalized as to be vulnerable to this increased digestive activity. The result is that inflammatory fibrous tissue (gummas, the shells of tubercles, etc.) undergo softening and liquefaction, as well as the exudates and secretions, followed by absorption, if their escape is otherwise impossible.

While the most marked and spectacular effects of the iodids are observed in tertiary syphilis, their administration is also indicated in the treatment of early syphilis for their effects upon exudates not yet advanced to the stage of fibrosis. Their use, however, is not limited to syphilis, since they are useful in other infections as well. It is to be noted, however, that the iodids have no influence upon completely healthy tissues; therefore, their administration does not influence ordinary scars and possibly not even the scar tissue of infectious processes, if the cells are entirely free of the effects of bacterial toxins or other agents and to all intents and purposes normal tissue even though the result of originally pathological processes.

CHAPTER LVII

TOXICOLOGY OF THE IODIDS IN RELATION TO THE TREATMENT OF SYPHILIS AND OTHER DISEASES

Fortunately the iodids are much less toxic than the organic arsenicals, mercurial and bismuth compounds employed in the treatment of syphilis, and consequently they are less dangerous and their administration is not followed as frequently by ill effects. Some individuals, however, possess a natural hypersensitiveness to the iodids so that even small doses may produce toxic reactions and, since most cases of syphilis or other diseases calling for iodid therapy require a prolonged administration of the drugs, ill effects are likely to develop in any case; while these are seldom dangerous, they may be very disagreeable and the whole subject is worthy of close attention in relation to the iodid therapy of disease.

Toxicity of the Iodids for the Lower Animals.—Enormous doses of sodium or potassium iodid may be administered to rabbits and rats by stomach tube without any discernible ill effects other than progressive loss of weight and emaciation upon prolonged administration. This is apparently largely due to disturbances of the gastro-intestinal tract with loss of appetite, as well as to an influence upon the thyroid gland and metabolism.

By intravenous injection, the maximum tolerated dose of potassium iodid for white rats has been in my experience about 0.310 gm. per kilo of weight administered as a 4-per cent. solution in water; this corresponds to over 18 grams per 60 kilograms or approximately 132 pounds. Potassium iodid is seldom administered to human beings by intravenous injection, preference being given the less toxic sodium iodid, but when injected, the dose should not exceed 2 or 3 grams in order to leave a good margin of safety.

Sodium iodid is about eight times less toxic since the maximum single tolerated dose administered as a 60-per cent. solution, is about 2.4 gm. per kilo which corresponds to the enormous amount of more than 144 grams per 60 kilograms or 132 pounds. Since the maximum dose injected intravenously in the treatment of human beings is seldom more than 20 grams, it is apparent that this dose is at least seven times less than the toxic dose for rats. Sodium iodid, therefore, is always to be preferred for intravenous injection.

By repeated administrations to rabbits, however, the toxicity of sodium and potassium iodids are about the same. For example, rabbits have stood daily amounts of potassium iodid by stomach tube as large as 0.24 gm. per kilo for 36 doses in succession; curiously, sodium iodid was less well borne by this route as the majority of animals succumbed. By intravenous injection rabbits have stood bi-weekly injections of potassium iodid in dose 0.10 gm. per kilo for 12 injections; sodium iodid was tolerated in about the same degree.

Just why there is this big difference in the toxicity of single doses of potassium and sodium iodids by intravenous injection is not definitely known. Possibly it is due to the more rapid elimination of sodium iodid or to the fact that the potassium ion is dissociated and more toxic than the sodium ion. Of interest in this connection is the fact that I have found sodium chlorid tolerated by white rats injected intravenously in doses as high as 1.5 gm. per kilo in 10-per cent. solutions, whereas potassium chlorid was 30 times more toxic being tolerated in doses of only 0.050 gm. per kilo. Sodium chlorid in dose of 2.0 gm. per kilo was immediately lethal; potassium chlorid was immediately lethal in dose of 0.1 gm. ker kilo. These results suggest that the chief reason for the great variation in toxicity of sodium and potassium iodids is the greater toxicity of the potassium ions. As will be discussed presently, potassium iodid is likewise more hemolytic than sodium iodid which may be an additional reason for its greater toxicity. Clinical experience has shown that potassium iodid and sodium iodid are tolerated about equally well by ingestion; possibly sodium iodid is less irritant and better tolerated. It is to be noted, however, that the toxicity of both compounds for rabbits by repeated intravenous injections and by ingestion does not vary nearly as much as by single intravenous injections.

Pathological Tissue Changes Produced in the Lower Animals by the Iodids.—As stated in Chapters XLVII, LII, and LV, the administration of arsphenamin and its substitutes, mercury compounds and bismuth compounds may result in important tissue changes in the internal organs of great interest in relation to chemotherapy and of practical importance in relation to the treatment of syphilis. There is much less reason for expecting, from clinical experience, that the iodids produce pathological tissue changes, but since they are frequently administered in large doses over prolonged periods of time, Lucke and I thought it well worth while to study the histological effects produced by potassium iodid and sodium iodid administered to rabbits by ingestion and intravenous injection.[1] Very little work has been done in this field, although Boehm[2] and Sgalitzer[3] have touched upon it briefly in pharmacological studies with the iodids. The results of our studies have shown that the administration to rabbits by stomach tube of potassium and sodium iodid in repeated large doses equivalent to approximately as much as 15 gm. per 60 kilograms of body weight, and repeated intravenous injections in amounts approximately equivalent to as much as 1 gm. per 60 kilograms, as well as single intravenous injections in amounts equivalent to approximately 30 gm. per 60 kilograms, did not cause tissue changes in the brain, heart, and suprarenals. The kidney, liver, lung and spleen showed slight tissue reactions which may be interpreted as the result of a mild irritation. Dosage, compound and route of administration did not produce any essential differences in the histologic changes.

An Etiological Classification of the Toxicological Effects of the Iodids.—It is apparent, therefore, that both potassium and sodium iodids do not produce any chemopathological tissue changes of note in the internal organs when administered in ordinary doses even over long periods of time. The iodids, however, are not lacking in local and general toxic effects, but we have but little information on the nature and mechanism of their production although their clinical manifestations are well known. Among the known toxicological factors may be mentioned the following:

1. Direct irritation of mucous membranes as of the gastro-intestinal canal by ingestion due to the iodids as such, to free iodin or impurities.
2. Irritation by dissociated ions and particularly by potassium after intravenous injections of potassium iodid.
3. Irritation of excretory organs as the mucosa of the respiratory tract, conjunctivæ, salivary glands, gums and skin.
4. Interference with excretion and particularly by nephritis.
5. Effects upon metabolism and the thyroid gland.
6. Intravascular hemolysis when iodids are injected intravenously in large doses.
7. Increased proteolytic activity with liquefaction necroses in areas of infection.
8. Production of Herxheimer reactions.
9. Iodid hypersensitiveness.

These factors may be now briefly discussed with more detail.

Direct Iodic Irritation.—That the iodids are capable of exciting irritation of mucous membranes with congestion, edema and serous exudation is seen clinically by gastric disturbances of pain, nausea and vague distress after ingestion. Concentrated doses in powders, pills, cachets, tablets, etc., produce much more irritation than diluted solutions and the last mentioned are always preferred for administration. Intestinal irritation is much less common, but does occur even to the extent of producing colic and diarrhea. The effects of local irritation are also to be observed when the iodids are administered by rectal injection.

It is possible that some of these effects are due to the liberation of free iodin in the stomach; also to the presence and effects of iodates.

When potassium iodid is injected intravenously the depression of the central nervous system and heart are generally ascribed to the potassium ions since the effects do not seem to be more poisonous than other potassium salts; at least these disturbances are produced only by very large doses in the lower animals and are not ordinarily observed in human beings.

Very probably the iodids are also capable of producing a similar irritation of the organs and cells concerned in their elimination and in this manner produce salivation by irritation of the salivary glands and especially the parotids; stomatitis, by irritation of the buccal mucosa; coryza, by irritation of the nasal mucosa; bronchitis and faucial edema, by irritation of the pharyngeal and laryngeal mucosa; conjunctivitis, by irritation of the conjunctivæ and a whole host of skin disorders, by irritation of the sweat and sebaceous glands.

Anything interfering with elimination by the kidneys and liver, and especially nephritis with retention, naturally throws an added weight upon the skin and these mucous membranes, which tends to increase the local irritant effects.

Iodic Disturbances of Metabolism and of the Thyroid Gland.—Naturally, if these effects are prolonged, one may expect to observe a loss in weight, anorexia, mental depression, irritability, loss of sexual power, etc., along possibly with nervous excitation and tachycardia due to disturbances of the thyroid gland. Indeed, one must exercise due care in the selection of patients for intravenous injections of sodium iodid, insofar as the thyroid gland is concerned, in order to avoid accidents from this source; in this connection I may mention that Schaffer[4] has recently observed the precipitation of hyperthyroidism in a patient with unsuspected adenomas of this organ following intravenous injections of sodium iodid and he advises extreme caution in the presence of even the smallest palpable nodule in the gland.

Otherwise, however, the metabolism of patients is not liable to suffer. Chistoni[5] found that there may be some increase of urea, total nitrogen, uric acid, purin bases and chlorid excretion and recently Crabfield[6] has stated that multiple small doses of both potassium and sodium iodid may double and treble the nonprotein nitrogen of the blood, the increase beginning about the second or third day, continuing for four or five days, and thereafter gradually returning to the previous level; the chlorids remained unchanged. Single doses were without these effects, which were apparently associated with an adjustment of the body fluids to the iodid in the blood and probably with some renal retention of nitrogen.

Iodic Hemolysis.—When potassium or sodium iodids are given by intravenous injection, it is possible that some minor reactions may be produced by the effects of hypertonic solutions, to proteins in the water and to intravascular hemolysis. I have found that 2 c.c. of 1:24 solutions of potassium iodid in saline causes the partial hemolysis of 1 drop of unwashed human blood while sodium iodid is less hemolytic (1:8). Washed corpuscles are much more susceptible and it may be that the serum effectually prevents intravascular hemolysis altogether; at least intravenous injections of human adults with 100 to 200 c.c. of 10-per cent. solutions of sodium iodid have not produced reactions suggesting sufficient hemolysis to produce lesions and symptoms. Agglutination of corpuscles does not occur.

Iodic Proteolysis.—Since the iodids are especially retained by devitalized pathological tissues and their exudates and secretions, it is not surprising that some of the toxicological effects of the iodids are due to increased pro-

teolysis of these substances as the result of removal of antiferment by the saturation of the unsaturated fatty acids by iodin. I believe that this accounts for the occasional appearance of urethral discharges in cases of chronic gonorrhea, the increased coryza and bronchitis of chronic rhinitis and bronchitis, the lighting up of latent foci of infection of joints with articular and periarticular swellings, the lighting up of latent infections of nerves with the production of neuritis, etc., sometimes following the administration of iodids in the treatment of syphilis and other diseases.

Iodic Jarisch-Herxheimer Reactions.—It is possible that the iodids may intensify syphilitic lesions, not only by a direct stimulation of spirochetes, but more indirectly by their effects upon syphilized tissues. These results, however, are not at all probable when the usual small doses of the iodids are given by ingestion. The iodids do not ordinarily increase the degree of complement fixation in syphilis or the cells in the spinal fluid in neurosyphilis, which are probably more sensitive indices of stimulated spirochetic activity than clinical lesions and symptoms. On the other hand, the cutaneous lesions of syphilis may undergo exacerbation during iodid therapy and it is possible for Herxheimer reactions to occur, but not with any thing near the frequency with which they may be observed after the administration of arsphenamin and its substitutes and mercury.

Iodic Hypersensitiveness.—And finally, one of the most important and frequent causes for untoward effects from the iodids is natural hypersensitiveness, analogous to the natural hypersensitiveness displayed by some individuals to arsenic, mercury, quinin, etc. The literature contains numerous descriptions of cases in whom iodism was brought on by very small doses of the iodids administered by ingestion. Some of the earliest experiments on the mechanism of drug allergies were inspired by clinical examples of hypersensitiveness to iodoform and other iodin compounds with the general result that it has been shown that guinea-pigs may be sensitized and shocked by injections of guinea-pig serum previously iodized in the test-tube. Friedberger and Ito[7] even claim that guinea-pigs sensitized with iodized guinea-pig serum may be shocked by injections of sodium iodid, iodoform and Lugol's solution; likewise, that guinea-pigs may be sensitized by injections of Lugol's solution to injections of iodized serum, but not to Lugol's solution itself. Indeed, more work has been done on iodid and iodin hypersensitiveness than with any other form of drug allergy, but all attempts have failed to transfer the hypersensitive state from human beings to guinea-pigs by injections of human serum.

Apparently, hypersensitiveness to the iodids may be acquired; at least, one sometimes observes marked intolerance after iodids have been taken for some time and even after periods of rest, when one may be reasonably sure that the effects are not due to accumulative toxicity. Curiously enough, large doses are sometimes better borne under these conditions than small doses, a fact to which I will again refer in more detail in Chapter LXV devoted to a consideration of methods of administration of the iodids.

Clinical Classification of the Toxic Reactions Produced by Iodids.—In the great majority of instances the toxic manifestations of iodism are mild and comprise a slight degree of salivation with a metallic or salty taste of the saliva, coryza and a few scattered acneiform lesions of the skin of the face and neck. These effects are apparently due to the excretion of the iodids through the salivary glands and particularly the parotids, and the mucosa of the upper respiratory tract. It is an easy matter, however, to overlook mild symptoms of this kind or the patient may fail to report them or coöperate properly with the physician, in which case severer and even dangerous symp-

toms may develop if the administration of iodids is continued. Likewise, severe and even alarming lesions like faucial edema may develop in those hypersensitive to the iodids even after the ingestion of small amounts.

There is, therefore, quite a long list of the possible toxic reactions produced by the iodids, but since permanent tissue injuries are uncommon, most of these quickly disappear when the administration of the drug is topped. Furthermore, the majority are uncommon and especially the severe lesions. They may be classified as follows:

1. *Disturbances of the Digestive and Accessory Organs*
   - (1) Metallic or salty taste
   - (2) Slight salivation
   - (3) Parotid irritation and "iodic mumps"
   - (4) Stomatitis
   - (5) Gastro-intestinal irritation
2. *Disturbances of the Respiratory and Accessory Organs*
   - (1) Rhinorrhea
   - (2) Coryza and "iodic grippe"
   - (3) Conjunctival catarrh
   - (4) Faucial edema
3. *Disturbances of the Skin*
   - (1) Iodic acne
   - (2) Iodic erythema, urticaria, bullæ, etc.
   - (3) Iodic purpura
4. *Disturbances of the Thyroid Gland (Hyperthyroidism)*

This list appears quite formidable and may readily enough give the impression that the iodids are dangerous drugs capable of producing a host of ill effects. But it includes the more uncommon toxic manifestations and, as previously stated, iodism in practice seldom proceeds beyond the stage of mild coryza, a mild acne and a few vague pains and "tightness of the jaws" in the neighborhood of the parotid glands. But if one were to include in a classification even a part of the large number of accidents and ill effects ascribed to the iodids in the literature, like hemiplegia, impotence, nephritis, etc., the list would be even larger; many of these, however, are now known to be due to syphilis or mercury and erroneously ascribed to the iodids which may have been given at the time; or they have been due to the physiological effects of the iodids upon pathological tissues without being toxic effects, although readily enough interpreted as being toxic manifestations.

Symptoms and Treatment of Toxic Iodid Reactions.—*Iodic taste* is a disagreeable salty or metallic taste, most common in the morning and especially complained of by women. It is due to the excretion of iodid in the saliva. Halitosis or odorous breath is not usually present although the patient frequently suspects that it is on account of the taste. It rapidly disappears when the administration is stopped or the dose reduced.

Iodic salivation is usually slight and mild, without halitosis or inflammatory changes of the gums and buccal mucosa. It is due to irritation of the salivary glands, and especially the parotids, by the excretion of iodids.

Parotid irritation is usually in the form of diffuse vague pains at the angles of the jaw. Women are especially likely to complain of vague neuralgic pains or "tightness" about the jaws which are difficult to describe or locate. Sometimes the pains are located in the gums, although the teeth and gums appear healthy. I believe that these are due to irritation of the parotid, sublingual and submaxillary glands by the excretion of iodid. They may make it impossible for the patient to take more than a very small daily dose; they usually disappear quite promptly when the administration is stopped. Rarely, fluctuating swellings of the glands occur which I ascribe to hypersecretion with blockage of the ducts; when the parotids are so involved the condition is frequently designated as "iodic mumps."

Iodic stomatitis and *gingivitis* are quite rare, because the iodids are not deposited in the buccal and gingival mucosa as are mercury and bismuth. Inflammatory changes and even ulceration may occur, however, in severe neglected cases of iodism or in cases of hypersensitiveness to the iodids. The lesions quickly disappear upon withdrawal of the drug and the use of simple mouth washes.

Gastro-intestinal irritation is expressed in the form of vague abdominal "uneasiness" or pain, along with anorexia, coated tongue and headache. Constipation or diarrhea may be present and the salty, metallic taste of iodid is especially disagreeable. These symptoms are not produced by intravenous injections and are apparently due to direct irritation of the gastro-intestinal mucosa by the drug administered by ingestion. In treatment constipation and dietary errors should be corrected, if present. The dose may require reduction although, curiously enough, the symptoms may disappear when the dose is increased. It is sometimes advantageous to give the drug about one-half hour before meals instead of after meals as is the usual custom. A special effort should be made to disguise the taste of the drug; I have found it advantageous to give it in a small glassful of cold ginger-ale or sarsaparilla.

Iodic rhinorrhea is the most common symptom of all; indeed, few patients escape it when large doses are given. In mild form the discharge is thin and serous and seldom muco-purulent. The nose is obstructed, due to congestion and edema of the mucosa and this may produce sneezing and radiating pains in the frontal sinus, headache, etc. as in hay-fever. Due care must be exercised in administering iodids to individuals with sinus infections. In its milder forms it is nothing more than an inconvenience and may pass away spontaneously; it is generally necessary to stop the drug for a few days and then resume with a smaller dose.

Iodic coryza, however, may develop and especially if the patient is hypersensitive to the iodids. This condition may be serious, inasmuch as the nasal discharge and swelling of the mucosa may be excessive, with a great deal of sneezing, edema and congestion of the eye lids, violent headache, etc. I have known sinus infections to follow and in some cases, latent infections of the antra, frontal and ethmoid sinuses have been aggravated. Treatment consists in promptly stopping the drug. In some cases it is necessary to reduce the turgescence by spraying the nose with a weak solution of adrenalin chloride like equal parts of 1:1000 solution and rose water with 10 grains of antipyrin to the ounce. Small doses of belladonna or atropin may be helpful in the form of the usual coryza tablets.

Conjunctival catarrh and iodic edema of the face usually develop in cases of severe iodic coryza. The eye-lids and conjunctiva are red, swollen and may itch or smart as in hay-fever, along with a thin watery secretion. A peculiar but characteristic edema of the tissues below the eyes may develop along with redness of the nose; the edema and redness of the eye-lids, associated with the conjunctival changes and erythema of the nose, fever, headache, fulness of the head and shooting pains, sometimes resembles an outbreak of urticaria or even erysipelas. It is difficult to explain these lesions; I have considered them due primarily to blockage of the lacrymal apparatus and conjunctival drainage by the involvement of the nasal mucosa. Possibly they are due in small part to irritation of the lacrymal glands by iodid since the drug may be found in the tears. Fortunately the lesions and symptoms quickly disappear when the drug is stopped.

In exceptional cases a train of symptoms like coryza, epiphora, sore throat, dyspnea, mild fever, malaise and severe headache resembles an attack of

influenza or "grippe" and are sometimes designated as "iodic grippe." The condition may be readily enough mistaken for an attack of tonsillitis or influenza, but the body pains are usually absent, the condition develops suddenly and subsides rapidly when the drug is stopped. In rare instances of extreme hypersensitiveness to the iodids the edema may involve the uvula, glottis and fauces in general, producing *acute laryngeal and pulmonary edema* characterized by dyspnea, stridor, cough, etc. Most recorded cases have developed after the first and second doses and with amounts as little as 3 to 15 grains. Tracheotomy has been required in some instances. I have never seen a case of this kind, but surmise that intramuscular injections of 0.5 to 1 c.c. of 1:1000 adrenalin may give relief.

Iodic acne is one of the most common manifestations of iodism and in mild form consists of a few scattered red pimples with pustular tops usually in the skin of the face and neck and rarely on the trunk and extremities. They tend to recur, but may disappear spontaneously even when the dose is raised. In some cases, however, these acneiform pustules become so large and numerous that the dose must be sharply reduced or the administration stopped, at least temporarily. In exceptional cases the eruption is purpuric (*iodic purpura*) with a predilection for the anterior surface of the legs and occurring symmetrically as discreet, miliary petechiæ of deep red color, painless, without itching and not disappearing under pressure. Occasionally the eruption is *bullous*, *eczematous*, nodular and tuberose, furuncular, fungoid, ulcerative or polymorphous. Due care must be exercised in differential diagnosis from syphilids, in which the sudden onset, forms, bright red areolas, softer bases, etc., of the iodic eruptions, along with their rapid disappearance when iodid ingestion is stopped, are useful differential points.

The cause of these eruptions has been a subject of much speculation and some investigation. They have been usually ascribed to irritation of the sweat and sebaceous glands by free iodin supposed to be liberated from the iodid by chemical action in these structures. Some investigators state that iodid is to be found in the pus of the lesions but Wile, Wright and Smith[8] have recently stated that this is an error probably due to contamination with iodid in the sweat.

As pointed out by Engman and Mook,[9] iodid acne is especially likely to develop in seborrheic and acne areas and areas of previous inflammation or injury; in their opinion the glands and follicles of the skin take no specific part in the production of the lesions. They suggest that iodids may cause some disturbance of equilibrium in the blood with the production of a toxin, which in turn causes irritation and various local inflammatory lesions. Wile and his associates do not regard the lesions as due primarily to the excretion of iodid or the activities of bacteria, but to some undiscovered complex biochemical reaction.

In my opinion, the pustular lesions at least are due to direct iodid effects in the skin as a result of the presence of the drug in the glandular secretions acting upon tissues of lowered vitality as a result of predisposing injuries so small as easily to escape detection, as black heads and minor bacterial infections of the sweat and sebaceous glands, but sufficient to favor increased proteolytic activity in the devitalized cells as a result of reduction in antiferments by the iodids; this results in increased proteolysis, with consequent irritation due to the products of digestion plus those due to secondary infection of the lesions with the staphylococci of the skin. I believe this mechanism explains the production of the acneiform, furuncular, fungoid and ulcerative lesions, as it does the production of local pustular lesions in syphilitics and non-syphilitics alike when given intracutaneous injections of luetin or other

substances while under the influence of iodids. The erythematous, bullous and hemorrhagic lesions are probably due primarily to toxic effects upon the nerves and capillaries comparable to the production of arsenical dermatoses. As in the bromid eruptions, these various lesions may develop after the administration of iodids has been stopped, but they usually occur during their administration.

In the treatment of these cutaneous disorders it is generally necessary to stop the ingestion of drug along with eliminative measures and the internal administration of Fowler's solution. They are rarely dangerous, not nearly as dangerous as the arsenical dermatoses and especially dermatitis exfoliativa. In severe cases it may be worth while to try intravenous injections of 1 gram of sodium thiosulphate in 10 c.c. of sterile water or saline, daily, for three or four doses.

Disturbances of the thyroid gland are in the nature of *hyperthyroidism* with tachycardia, tremors, and the usual signs and symptoms of this state in general. They are apparently of rare occurrence and likely to develop only in those cases with various forms of thyroid enlargement and hyperactivity. In reading over some of the case reports of nervous disturbances ascribed to iodids, one is impressed with the possibility of these being really due to hyperthyroidism when occurring in mild degree although usually ascribed to the effects of iodids upon the nervous system. Other case reports on the effects of iodids upon the nervous system read as if they were the manifestations of syphilis and neural Herxheimer reactions.

CHAPTER LVIII

JARISCH-HERXHEIMER REACTIONS AND SYPHILITIC RECURRENCES

In the preceding chapters mention was frequently made of Jarisch-Herxheimer reactions and syphilitic recurrences in connection with the toxic reactions sometimes produced by mercury, arsphenamin and its substitutes and bismuth. In view of the practical importance of these subjects in relation to the diagnosis of toxic reactions and their treatment, as well as the treatment of syphilis itself, it may be well to discuss the subjects more fully.

Jarisch-Herxheimer Reaction.—In 1895, Jarisch[1] published a long series of cases of syphilis presenting roseola in whom the eruption became more marked and distinct during the administration of 2 to 5 daily inunctions of mercury. Apparently, however, these observations attracted little or no attention and not even Fournier appears to have noted or commented upon thin occurrence. A few years later Jadassohn[2] published similar observations

and in 1902, Herxheimer and Kraus[3] published such a complete account of the phenomenon as to attract considerable attention. They noted that in cases of secondary syphilis the injection of the first large dose of an insoluble salt of mercury was sometimes followed in fifteen to twenty-four hours by a change in the appearance of the skin rashes in which the lesions became larger and more prominent. Roseolar spots, formerly not noticed, became apparent; erythematous papules resembled urticarial lesions and the rashes sometimes became confluent and changed in color from a dusky to bright red. The authors stated that the reaction occurred only after the first injection of a large dose of mercury and not after the second or subsequent injections and showed that it was not due to mercurial poisoning.

Soon after the discovery of salvarsan, Finger[4] described the reaction following injections in the secondary stage of syphilis and the reaction has since became widely known as the Jarisch-Herxheimer reaction.

It is now well known that the reaction may be also produced by the various salts of bismuth being employed at present in the treatment of syphilis, but injections of arsphenamin, neoarsphenamin and their substitutes produce the reactions more prominently and frequently than either mercury or bismuth, while they have not usually been produced by the iodids at all. The administration of mercury by mouth usually does not produce the reaction, as likewise small subcutaneous injections or mild inunctions; it is highly probable that for these reasons Fournier and other syphilologists apparently did not observe the phenomenon or passed over the reactions as due to the natural cause of syphilis.

The *original* Jarisch-Herxheimer reaction, therefore, referred only to an exacerbation of the skin and mucous membrane lesions of the secondary stage of syphilis, and when the reaction occurred after an injection of arsphenamin it was noted that the skin or mucous membrane at the site of the lesion became turgescent and might weep, particularly if it were an infiltrated lesion. Usually within two to four hours after injection a roseolar eruption appeared or, if present, it became more prominent and papular and was regarded as a toxic dermatitis of the erythema multiforme type. As a rule, however, the macular rash disappeared in six hours while pre-existing lesions remained larger, redder and occasionally edematous. The pigmented syphilids might become more prominent and while the mucous membrane lesions reacted less frequently, yet they might undergo similar changes.

The *modern* Jarisch-Herxheimer reaction, however, includes not only these skin and mucous membrane exacerbations of the secondary stage of syphilis, but also the exacerbation of tertiary lesions of the skin and mucous membranes and of the internal organs as well. Reactions of this kind have become particularly prominent since the widespread adoption of the organic arsenical compounds in the treatment of syphilis and their occurrence in important organs as the cranial nerves and other parts of the central nervous system, may be not only dangerous but likely to be interpreted as an expression of toxic effects of the drugs.

Clinical Manifestations of Jarisch-Herxheimer Reactions. (*a*) *In the Primary and Secondary Stages of Syphilis.*—The typical and original reaction refers to the exacerbation of the skin and mucous membrane lesions of the secondary stage of syphilis along with an exacerbation of the glandular lesions in some cases (enlargement with pain and tenderness); these reactions have been described above, are not dangerous and of relatively slight importance.

It is highly probable, however, that a similar reaction takes place wherever the spirochetes happen to be located elsewhere in the body and in the

meninges, may result in the production of headache, increased amounts of spinal fluid with an increase of cells and an increase of protein. Even in the primary stage of syphilis one may observe an increase in the activity of spirochetes in the secretions during the first one to six hours after an injection of arsphenamin, although an enlargement of the lesions with exacerbation of the inflammatory phenomena may or may not occur.

(*b*) *In the Tertiary Stage of Syphilis.*—Not infrequently, however, similar and clinically more important reactions may occur in the tertiary stage of syphilis. Sometimes when the treatment of chronic latent syphilis is begun by the intravenous injection of 0.4 to 0.6 gm. arsphenamin or 0.6 to 0.9 gm. neoarsphenamin, the patient complains of tenderness of the inguinal lymph-glands, of vague pains in the region of the heart or elsewhere and these have usually impressed me as being the result of exacerbations of low grade chronic inflammatory lesions in these tissues.

It is particularly important to bear in mind that in active tertiary syphilis the administration of these drugs in large doses may result in an exacerbation of the lesions. Gummata, when not open, may become swollen and turgid; when ulcerated, they may enlarge and discharge an abundant serous exudate. Such lesions occurring along the skeletal system, in the nose, etc., do no particular harm but lesions of the central nervous system may be dangerous. In tabes the reaction may consist of intense pains due to involvement of the posterior spinal roots, which appear from one-half to one hour after injection and may last for a day or two. Gastric crises may be precipitated and the pains prove so severe as to require morphin although it has been noted that a second smaller dose of arsphenamin may afford relief. In cerebral sphilis the reaction may be manifested by intense headache and an exaggeration of focal symptoms and paralyses. When a cranial nerve which passes through a bony canal is involved, the resulting swelling may lead to paralysis, as sometimes happens with the auditory and facial nerves.

Reactions of this kind may be confused with neuro-recurrences or neuro-recidives and indeed, the pathological changes appear to be identical in both. In Herxheimer reactions, however, the lesions are produced a few hours after treatment is given due to an exacerbation of inflammatory phenomena; in syphilitic recurrences the lesions follow some days or weeks after cessation of treatment due to a resumption of activity on the part of spirochetes which have escaped destruction.

In chronic syphilitic myocarditis the reaction is manifested by pain and precordial distress; in the liver, by the development of constipation, "dyspepsia," anorexia and jaundice or, at least, a shallow sub-icteric coloring of the skin and mucous membranes. General symptoms at this time may be vague aches and pains in the extremities, malaise, loss of appetite, etc., which are so likely to be ascribed to the direct toxic effects of the drug administered but which in fact may be due to Herxheimer reactions of this kind and which pass away as treatment is continued.

(*c*) *Provocative Wassermann and Spinal Fluid Changes as Results of Jarisch-Herxheimer Reactions.*—Since the Jarisch-Herxheimer reaction appears to be in part at least the result of increased spirochetic activity it is to be expected that the Wassermann reaction with blood and spinal fluid may become stronger if already positive or, become positive if previously negative, and now well known as the "provocative" Wassermann reaction, previously discussed in Chapter XLI. It is very commonly observed that weakly positive Wassermann reactions in chronic latent syphilis become much stronger as treatment is given; I do not think that this is due to an effect of the drug upon the tissues with the production of such changes in

the blood as result in falsely positive reactions; rather I believe the reactions are due to an increased production of the Wassermann antibody or "reagin" as a result of increased spirochetic activity. It is much more common to observe weakly positive reactions becoming stronger after the first few doses of arsphenamin or neoarsphenamin, than to see negative reactions reversed to positive; indeed, as stated in Chapter XLI, several injections of neoarsphenamin may be required for producing the latter result because there are fewer spirochetes in the tissues, as indicated by the preceding negative reactions.

Spinal fluid changes in the nature of an increase of cells and protein, as well as of the Wassermann and colloidal gold reactions, have also been observed, due in part to the excitation of spirochetic activity.

As I shall discuss later, it is very important to follow up cases of these kinds with active treatment; merely to provoke a Wassermann reaction for diagnosis may arouse a latent infection with progression of the disease unless active treatment is continued.

Pathology of Jarisch-Herxheimer Reactions.—Very little can be written of the pathological changes occurring in the lesions of Jarisch-Herxheimer reactions, because of the scarcity of histological examinations and reports. Apparently there is an acute exacerbation of the inflammatory phenomena with acute hyperemia, serous exudation and an increase of infiltration of the tissues with small lymphocytes and plasma cells. The whole process including that of coagulation and liquefaction necrosis appears to be intensified. Perivascular infiltration is especially prominent, as likewise changes in the vessel walls tending to obliteration of the channels. The axis cylinders of nerves may be swollen and tortuous accompanied by infiltration of the sheaths with lymphocytes and plasma cells. The cells of an organ as of the liver and heart, may show albuminous or fatty degeneration as if subjected to the influence of an increased amount of toxic substances from the spirochetes, the drug or both.

Etiology and Nature of Jarisch-Herxheimer Reactions.—Many theories have been advanced to explain the mechanism of the Jarisch-Herxheimer reaction. The one mostly in favor and advanced by Wechselmann,[5] Ehrlich, Gennerich and others is that the reaction is due to an excitation of spirochetic activity in which the parasites increase in numbers and virulence along with the production of toxic substances in the nature of endotoxins from the destruction and disintegration of the parasites by the drug administered. Herxheimer and Kraus believed that the reaction was due to a hypersensitiveness of the cells in syphilitic foci to mercury, but of course this view was expressed before the discovery of *Spirochæta pallida* by Schaudinn.

The reaction is undoubtedly due in part, at least, to spirochetic activity. The pathological tissue changes, the finding of increased numbers of spirochetes by dark-field microscope examination of open lesions and the increase in degree of complement fixation indicate that this occurs, although there is little or no experimental support for the theory that the reaction is due to the liberation of endotoxins. The latter is merely a reasonable theory based upon analogy to the bacterial endotoxins.

But I doubt if this is the complete explanation of the mechanism. Hesse[6] and others, for example, have described reactions in non-syphilitic individuals with cutaneous eruptions similar to the Jarisch-Herxheimer reactions following the administration of arsphenamin in which the rôle of spirochetes could be excluded. It is well known that arsenic is vasculotoxic and by direct action upon the endothelium of capillaries or possibly by an effect upon the vasomotor center tends to produce vasodilatation which would naturally be particularly prominent and, indeed, may only occur, in areas of acute or

subacute inflammation. Furthermore, the spirochetes themselves produce vascular injuries and it may be that the Jarisch-Herxheimer reaction is a dual process due to the combined effects of both spirochetes and arsenic upon capillaries, but in which the rôle of spirochetes is of particular importance since the reactions do not tend to recur as the organisms disappear.

But is the Jarisch-Herxheimer reaction of this dual character in the case of mercury and bismuth? Neither of these drugs possess the same degree of vasculotoxic action of arsenic, but yet both, and particularly mercury, excite hyperemia and serous exudation in the tissues by their local irritant and corrosive action. Therefore, the presence of mercury or bismuth in the local lesions of syphilis may exaggerate the inflammatory phenomena of syphilis and I am of the opinion, as expressed in preceding chapters, that mercury tends to localize in syphilitic tissues by a process of specific organotropism or selective affinity for syphilitic exudates and *Spirochæta pallida* which we do not well understand at present. As previously stated, Herxheimer and Kraus thought that syphilitic tissues were hypersensitive to mercury; rather I believe there is this increased tendency for mercury (and possibly bismuth) to locate in syphilized tissues where they gradually reach a joint of concentration in which spirocheticidal effects are produced even though the drugs are not present in the blood or other tissues sufficient for producing toxic reactions. In addition to these local effects of mercury in syphilitic foci, there is the more important phase of exaggerated spirochetic activity, as in the reactions following the administration of arsphenamin and neoarsphenamin, and, as the parasites disappear, so does the tendency for Herxheimer reactions. But mercury and bismuth are far less likely to produce the reaction, because these drugs are absorbed more slowly and in small doses may bring about the destruction of the spirochetes without the production of Jarisch Herxheimer reactions at all.

The Jarisch-Herxheimer reaction, in other words, is analogous to the focal reactions of tuberculosis produced by tuberculin or focal reactions of other bacterial origin produced by the injection of autogenous vaccines. In these instances, the reactions are considered allergic in character, but the Jarisch-Herxheimer reactions are not because they occur in individuals who have never before taken the drugs and who present no evidences of natural allergy to them. But in both classes there is this increased affinity between the parasites and their destroyers; in the case of bacterial diseases, between the proteins of the vaccine and the antibodies engendered by them; in the case of syphilis, between the spirochetes and spirocheticidal drugs. Just as focal reactions in tuberculosis and other infections may be produced by large injections of sterile milk and other non-specific agents, because in the lesions the blood-vessels are more subject to dilatation, so likewise in non-syphilitic lesions may the vasculotoxic effects of arsenic be exaggerated, explaining the occurrence of Herxheimer-like reactions in non-syphilitic diseases treated with arsphenamin and its substitutes.

Diagnosis of Jarisch-Herxheimer Reactions.—The diagnosis of these reactions is not usually difficult since they bear an intimate time relation to the administration of anti-syphilitic drugs occurring in a matter of a few hours to a day or two after the injection of arsphenamin or neoarsphenamin or in from one to several days after the intramuscular injection of mercury or bismuth. Jaundice is particularly difficult of differential diagnosis because in hepatic Herxheimer reactions this sign develops slowly and in any given case may be due to syphilis and not to the drug.

Prevention of Jarisch-Herxheimer Reactions.—I have discussed this subject with more detail in Chapter LXXIV, because it is one of considerable

practical importance when the treatment of syphilis is instituted in the tertiary stage and particularly if the cranial nerves (the oculomotor, optic, auditory and facial nerves) are involved or if symptoms of tabes are present. Here it may be stated, however, that these reactions may be generally avoided by instituting treatment with small doses of the chosen remedy, that is, with 0.1 to 0.2 gm. of arsphenamin or neoarsphenamin instead of the usual 0.6 to 0.9 gm. doses or by commencing treatment with the administration of small doses of mercury before more vigorous therapy is attempted.

Treatment of Jarisch-Herxheimer Reactions.—Specific treatment is generally demanded and consists of the administration of more arsphenamin, neoarsphenamin or other antiluetic drug. It is true that this therapy demands courage on the part of both physician and patient, and it is sometimes particularly difficult for the latter to submit to another injection of a drug that brought on his pain and disability. But whenever the physician is reasonably sure that the reaction has occurred and is not a direct toxic action of the drug, it is proper and almost imperative in some cases to continue with specific medication. In such instances, however, it is my custom to give smaller doses but at more frequent intervals.

In addition it may be necessary to afford relief from pain in tabes by the administration of morphin. The headache of syphilitic meningitis may require rest in bed. Spinal puncture sometimes affords relief as likewise the internal administration of large amounts of sodium chlorid as described in Chapter LI for the treatment of hemorrhagic encephalitis.

Syphilitic Recurrences.—Syphilitic recurrences generally occur several weeks after the cessation of active antisyphilitic treatment. For this reason they are not usually confused with Jarisch-Herxheimer reactions, but may be, and frequently are, confused with the late toxic effects of the drug.

Syphilitic recurrences are due to a resumption of activity of spirochetes escaping destruction. It is possible, however, and indeed, probable, that these effects are aided by the production of localized areas of reduced tissue resistance by the toxic action of the drugs administered. There is, therefore, frequently the possibility of a dual etiological character to lesions of this kind and particularly in syphilis of the liver. Furthermore, insufficient treatment tends to depress immunological resistance in syphilis which may be an additional factor and especially in the recurrences of early syphilis. As mentioned in previous chapters, the development of immunity in syphilis depends upon the presence of living spirochetes in the tissues. This does not mean that we should leave syphilis untreated because the acquired immunity is probably never sufficient for effecting a cure, but it does mean that when we treat syphilis we should keep on treating until the spirochetes are destroyed. In other words, insufficient and inadequate treatment depresses immunity without removing the spirochetes and the latter may then spring into activity with greater dissemination as soon as specific treatment ceases; in this manner the question of kind and amount of treatment bears an additional and important relation to syphilitic recurrences.

Syphilitic recurrences of the nervous system are generally designated as "neuro-recurrences" or "neuro-recidives" and, are discussed more fully in Chapter LI in relation to neuritis sometimes produced by the organic arsenical compounds and with which they are particularly likely to be confused; recurrences in the liver are designated as "hepato-recurrences" or "hepato-recidives" and are discussed in the same chapter. Recurrences after courses of mercury and bismuth are more apt to be true syphilitic recurrences, because these drugs are much less likely to produce neuritis, hepatitis and allied lesions due to the toxicity of the drugs.

Syphilitic recurrences are more likely to develop in the tertiary stage of the disease when treatment is started and then interrupted. Therefore, in cases yielding positive "provocative" Wassermann reactions, treatment should always follow. Recurrences are likely to occur in the oculomotor, optic, auditory and other cranial nerves due to syphilitic activity and the laying down of increased numbers of lymphocytes and plasma cells in the sheaths; in cases of this kind, there is usually no suspicion of toxic effects on the part of the drug administered if it happens to be arsphenamin, neoarsphenamin, mercury or bismuth, because these compounds do not usually produce toxic amblyopias in case the optic nerves are involved or similar lesions of other nerves.

But if one of the pentavalent organic arsenical compounds have been administered, and particularly atoxyl or tryparsamid, due care must be exercised in diagnosis because these compounds are especially likely to produce toxic amblyopias, as discussed in Chapter XLVI.

The *treatment* of syphilitic recurrences demands the administration of antiluetic drugs providing one can be sure that the condition is a true recurrence due to spirochetic activity rather than due to some toxic effect of the drug. In case of doubt, it is well to resume treatment with some other agent. For example, in cases of recurrences of the optic and auditory nerves or other parts of the nervous system as well as in liver recurrences, following courses of arsphenamin or neoarsphenamin, it is my custom to institute treatment with a course of injections of potassium tartro-bismuthate or of mercury by inunction. In this manner, one escapes making the mistake of possibly adding to the toxic effects already produced by arsenic.

PART IX

VARIOUS METHODS FOR THE ADMINISTRATION OF ANTISYPHILITIC MEDICAMENTS

CHAPTER LIX

TECHNIC OF VENOUS PUNCTURE AND OF GRAVITY AND SYRINGE METHODS FOR INTRAVENOUS INJECTIONS

The technic of intravenous injections has undergone many improvements and refinements during the past fifteen years since the introduction of arsphenamin and neoarsphenamin in the treatment of syphilis. Prior to that time it was the general custom to incise the skin and expose a vein, but this practice is not now resorted to except in unusually difficult cases. Many different kinds of apparatus and needles have been described, but the simplest are generally very satisfactory when the principles are understood and experience has been gained in the technic of venous puncture and intravenous infusions. As in all other fields of surgical practice, experience and practice are required for the highest proficiency in intravenous therapy and those lacking in experience should first work under the observation and with the assistance of one skilled in the methods. Venous puncture and intravenous therapy form a very important part of the modern treatment of syphilis and it is necessary for those physicians undertaking the treatment of this disease to perfect themselves in this work so that not only one, but a series of intravenous injections, may be given patients without scarring, undue pain and disability.

In this chapter I shall explain with considerable detail the methods which I have employed for several years with uniform success; these methods are applicable not only for the administration of the organic arsenicals but for mercury, the iodids and whatever other drugs may be administered by intravenous infusion.

Importance of Good Technic.—In no other field of intravenous therapy is it as necessary to possess as much skill and nicety in technic, as in the treatment of syphilis. If only one or two injections of arsphenamin or its substitutes were sufficient, most individuals would be willing to withstand almost anything in the way of pain and scarring, but such is not the case. It is now well established that a series of injections are required and it is therefore necessary to give these by the most painless methods free of "tell-tale" marks. The dreadful pain and disability resulting from large accidental perivascular injections of arsphenamin and neoarsphenamin imposes upon the physician a heavy responsibility in making the injections. There should be no compromise with make-shift apparatus, rusty and dull needles, defective syringes and short-cut hasty methods. The best is not too good and good work should never be sacrificed for mere speed.

It is especially necessary to avoid incising the skin and exposing veins on account of the resulting scars. In this day the laity are becoming quite well informed on the usual significance of scars about the elbows and the patient should be spared them whenever possible. This is especially true of women but of no lesser importance to men and especially those required to work with bared arms.

Choice of Veins.—In the great majority of cases the veins of the forearm and especially those about the elbow are employed as the median cephalic, median basilic, common ulnar and radial veins (Fig. 31). The median, ulnar and cephalic veins are also employed; indeed, any prominent, *well supported* vein may be used, but the median basilic is probably the least desirable for the inexperienced because of the proximity of the internal cutaneous nerve and because it is separated from the brachial artery by the biceps fascia which may be pierced by clumsy technic.

The most prominent vein is not always the easiest to enter because it may roll under the needle; under such circumstances it is especially advisable to use a short and very sharp needle. The best veins are those which are full but well supported by the subcutaneous tissues to prevent rolling and dimpling while the needle is being introduced.

In some cases the veins on the back of the hand may be employed; however, never by choice but only by necessity, since they are small, very thin, easily pierced and likely to give subcutaneous hemorrhages. The same is true of veins about the ankle. When these veins are employed the needle must be short, very sharp and not larger than gauge No. 20 or 22.

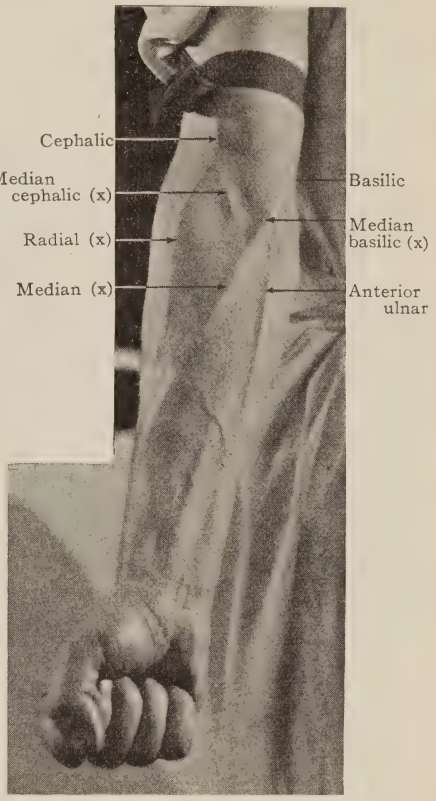

FIG. 31.—CHOICE OF VEINS FOR INTRAVENOUS INJECTIONS AND SECURING BLOOD.

The sites of choice are marked with an (x); it is always advisable to avoid punctures near the crease of the elbow in order to avoid subsequent discomfort.

Children from one to six years are the most difficult of all to inject intravenously because their veins are not only very small and usually well covered, but because they usually struggle during the operation. If the child can be induced to keep quiet one can frequently inject them with a small needle (No. 22) and syringe by way of a vein about the elbow; otherwise one may use the superficial temporal or the external jugular veins. Naturally one hesitates to use the latter because of the proximity of large vessels, but in practice the method is quite simple and safe.

In infants under a year the superior longitudinal sinus may be employed, but never as a matter of choice for the injection of arsphenamin or neoarsphen-

amin, because of the serious reactions and fatalities which have followed accidental injections into the substance of the brain from transfixion of the sinus. I believe that one of the external jugular veins is always to be preferred and if these cannot be used, intramuscular or even intraperitoneal injections may be resorted to. The intravenous injection of arsphenamin or one of its substitutes is rarely required as a life saving procedure as may be blood transfusion or the intravenous infusion of glucose or sodium bicarbonate, and for this reason I do not approve of jeopardizing the life of an infant by sinus injections of antisyphilitic drugs.

Position of the Patient.—In drawing blood for the Wassermann test and in giving intravenous injections of concentrated solutions of neoarsphenamin and sulpharsphenamin, the patient may sit upright alongside of a table with the arm extended and a support under the elbow (Fig. 32); if, however, the patient is nervous and feels that he or she may become ill or faint, it is better

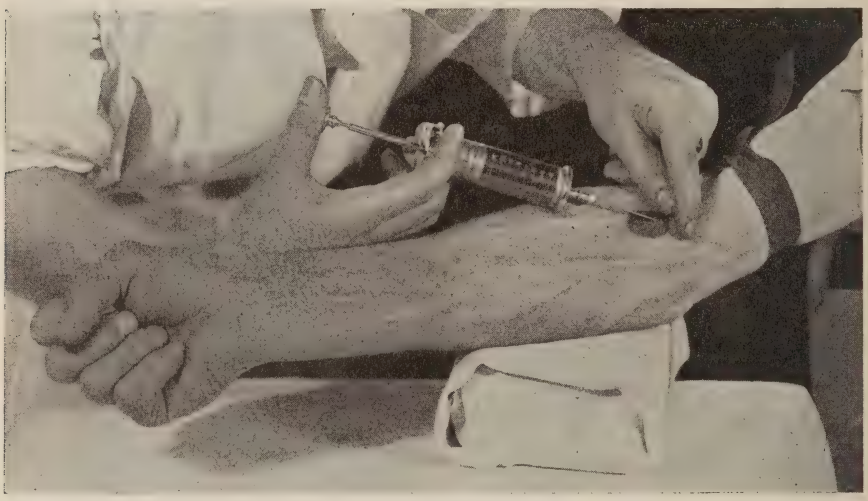

FIG. 32.—SITTING POSITION FOR INTRAVENOUS INJECTION OR WITHDRAWAL OF BLOOD.
The elbow is supported in order to secure maximum extension of the arm; the hand is rapidly opened and closed and finally clenched before puncture of the vein in order to render it full and prominent.

to have the patient lying on a table with the arm extended. Whatever the position may be, the patient should be as comfortable as possible and especially the arm, if the position must be maintained for five minutes or longer; otherwise movements may occur tending to displace the needle. The latter position is always advisable for gravity injections of arsphenamin and neoarsphenamin. In the prone position the patient is not as well able to watch the manipulations and it is always the position of choice for intravenous infusions by both syringe and gravity methods because it allays nervousness, enables the patient to assume a comfortable position and prevents accidents due to sudden faintness and nausea.

Application of the Tourniquet.—The practical importance of a proper tourniquet is not to be overlooked. It should be at least an inch wide in order to produce the minimum of discomfort and should be applied in such manner as may be released instantly and with no commotion in order not to disturb the needle and injection.

In many instances a tourniquet may be improvised by twisting a towel, a piece of bandage or the shirt sleeve and held by an assistant or the patient, but I regard these procedures as inferior to a piece of ordinary garter elastic or a strip of rubber sheeting held by a slip knot. Sometimes an assistant or even the patient himself may firmly grasp the arm and distend the vein sufficiently. The ordinary surgical tourniquet is too clumsy and generally unsatisfactory; the tourniquet of rubber tubing held by a hemostat is only a makeshift, apt to wrinkle and pinch the skin. The cuff of a sphymanometer makes a most excellent tourniquet, being broad and comfortable and readily applied and released.

My favorite tourniquet is 15 inches of good garter elastic about an inch wide applied with one firm turn and held by a slip knot (Fig. 33) which is

FIG. 33.—SHOWING THE DETAILS OF A SATISFACTORY SLIP KNOT TOURNIQUET OF ORDINARY GARTER ELASTIC.

released instantly by a slight pull without disturbance. The tourniquet should be applied flat without wrinkling or pinching the skin.

After applying the tourniquet the patient should open and close the hand vigorously for a few seconds and keep the hand clenched during the introduction of the needle; this aids in distending the superficial veins.

The tourniquet should not be applied too soon; all should be in readiness, as the most comfortable tourniquet becomes very uncomfortable as venous stasis is maintained over several minutes.

If the veins are small and deep, as in the case of obese women, it is sometimes helpful to apply an additional tourniquet from the wrist upward to the middle of the forearm (Fig. 34) after a tourniquet has been applied above the elbow. Under such circumstances it is also sometimes helpful to have the patient first bathe the hand and arm in hot water followed by

brisk rubbing, immediate application of a tourniquet and massage of the arm upward.

If the veins on the back of the hand are employed, it is well to first have the patient soak the hand in hot water for several minutes followed by brisk drying and the application of a tourniquet about the wrist.

If the external jugular vein is employed, an assistant is required to make compression of the neck just above the clavicle as shown in Fig. 43; an assistant may also distend a vein of the scalp by digital compression.

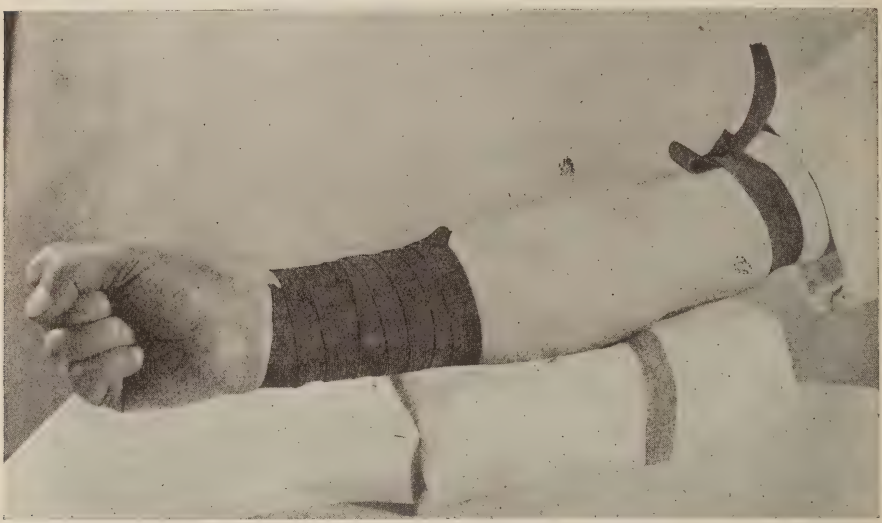

FIG. 34.—A DOUBLE TOURNIQUET SOMETIMES OF VALUE IN OBESE INDIVIDUALS OR THOSE WITH SMALL AND DIFFICULT VEINS.

Preparation of the Skin.—For simple venous puncture it is sufficient to prepare the skin by cleansing with 1:1000 mercurophen or bichlorid of mercury in alcohol; tincture of iodin (5 per cent.) or a solution of picric acid (5 per cent.) may be applied, but if so, they should be wiped away with alcohol so as not to hide the vein.

If it is necessary to incise the skin, there should be thorough preliminary cleansing with soap and water, following by iodin and a final cleansing with alcohol in order to guard against infection of the skin to prevent scar formation as much as possible.

Technic of Venous Puncture.—When all is in readiness, the tourniquet applied, vein selected and skin prepared the needle may be entered into the vein. If the patient is nervous and needle-shy, the site of puncture may be briefly sprayed with ethyl chlorid or a drop or two of sterile 1 per cent. solution of butyn may be injected *into the skin* with a 1 c.c. syringe fitted with a No. 26 needle. The latter, however, adds to the difficulties, may interfere with the vein puncture and great care must be exercised against puncturing the vein as perivascular bleeding will occur until the tourniquet is released, withthe production of a hematoma which interferes with subsequent puncture at this site. As a general rule no anesthesia is required for No. 22 needles and especially if a short sharp needle is employed; with No. 19 or larger needles, one or the other of these anesthetics may be required for nervous patients but this is exceptional rather than routine practice.

The vein should be steadied with the thumb and index finger; some physicians prefer to slightly stretch the skin over the vein to steady it although this tends to flatten the vein and increase the chances of transfixion. Various clamps have been devised for grasping and steadying the vein

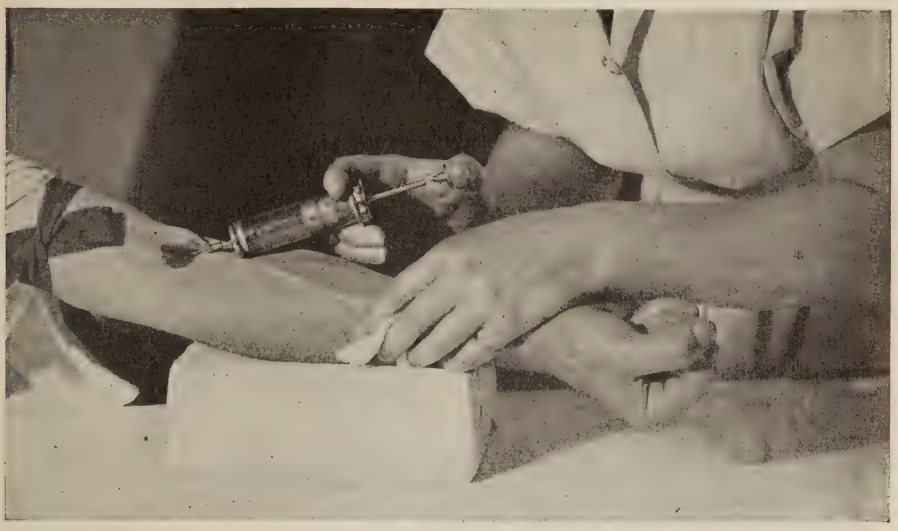

FIG. 35.—CORRECT ANGLE FOR HOLDING A SYRINGE FOR ENTERING A VEIN.
The syringe is held at an acute angle to the arm with the needle bevel upward.

FIG. 36.—INCORRECT ANGLE FOR HOLDING A SYRINGE FOR ENTERING A VEIN.
The syringe is being held at such an angle as increases the danger of transfixing the vein with the needle; the arm is poorly supported and the veins poorly distended.

through the skin but there is no better means than the finger and thumb of the disengaged hand.

The needle should be held at an acute angle to the arm (Fig. 35); it is a mistake to attempt entering the vein at a right angle because of the danger of passing through the vessel (Fig. 36). It is also good practice to puncture

the vein obliquely, that is, with the needle directed to the side of the vein rather than directly over its top and especially if the vessel is very prominent, sclerotic and freely movable. When an attempt is made to puncture directly over the vein the needle sometimes slips over its top and passes into the perivascular tissues. When, however, the vein is not prominent but is felt full and elastic in the subcutaneous tissues, one may enter the needle directly over the vein as the vessel is well supported and unable to roll.

When blood is being withdrawn or an injection is to be given with a syringe the needle should always be firmly attached, as the syringe affords an excellent handle for the needle. If an injection is to be given by gravity the

FIG. 37.—"FLASH" OF BLOOD SHOWING THAT THE NEEDLE IS WITHIN THE LUMEN OF THE VEIN.

unattached needle may be entered into the vein and the tubing attached when a free flow of blood is observed. If, however, a gravity injection is being given by a short Record or Luer needle, a sterile 5 or 10 c.c. syringe carrying saline solution may be loosely attached as a handle, the syringe being gently detached when a flow of blood into the syringe has been observed, and the tubing attached.

Evidence that the needle has entered the vein will be found by the fact that there is a peculiar "give-away" sensation to experienced fingers and blood appears in a *free* flow either from the needle or into the syringe as the piston is slightly withdrawn. The "flash" of blood (Fig. 37) should be free; if only a few drops appear it is almost sure that the lumen of the needle is not entirely in the vein. Sometimes a scanty flow of blood is due to partial

blocking of the vein but this is not at all likely if the needle has been tested before use as it should be; it is bad practice to pass a wire into the lumen while the needle is in place as an embolus may be thrown into the blood stream. The blood of tuberculous individuals having a high viscosity may not flow easily according to some physicians, but as a general rule no difficulties are encountered.

If the blood does not flow one may depress or rotate the needle, push it in a little further or withdraw it very slightly and enter it in a new direction, but if perivascular bleeding occurs, indicating that the vein has been pierced, it is well to loosen the tourniquet and withdraw the needle. After a few minutes the tourniquet may be re-applied and a fresh attempt made. Likewise if the needle is withdrawn because a "flash" of blood has not been observed, and bleeding follows from the wound, the tourniquet should be released at once and gentle pressure made over the puncture for a few minutes to prevent perivascular bleeding. The tourniquet may now be reapplied for a fresh attempt but it is always unwise to endeavor to puncture the vein at the same site and especially if a hematoma has been produced.

When blood is being withdrawn for the Wassermann test the tourniquet should not be released until the required amount is secured. *But the tourniquet should be always released before the needle is withdrawn in order to prevent subcutaneous and perivascular hemorrhage.* When an injection is to be given the tourniquet should be released, but with syringe injections this is not always necessary and should never be attempted at all if the arm must be moved with danger of displacing the needle. With slow injections the vein does not usually "balloon" and the tourniquet aids in bringing about slow admixture of blood and solution of drug. With gravity injections, however, the tourniquet should be always released to prevent "ballooning" of the vein and perivascular bleeding.

Methods for Obtaining Blood for the Wassermann Test. *With the Keidel Tube.*—One of the most satisfactory methods of obtaining blood from a vein quickly, aseptically and with the least pain is by means of the Keidel tube (Fig. 38). As made at present by Mr. Comer for the Steele Glass Company of Philadelphia, this very useful apparatus is available with a glass window permitting one to see a flow of blood, and thereby indicating that the vein has been entered, before the neck of the ampule is broken. The apparatus is dispensed sterilized and ready for use as follows:

1. The patient may sit alongside of a table or desk with the arm extended and elbow supported.

2. The tourniquet is applied above the elbow and the patient requested to open and close the hand vigorously.

3. The skin is wiped with cotton and alcohol.

4. The wire is removed and the hub of the needle grasped (avoiding contamination of the shaft) between the thumb and first finger (Fig. 38) and entered through the skin into the vein at an acute angle to the arm. It is a mistake to enter the needle at an obtuse or right angle because it may be passed through the vein.

5. As the vein is entered there is a peculiar "give-away" sensation readily appreciated by experience; if the "window" type of apparatus is employed a flow of blood is seen.

6. The long stem of the ampule in the rubber tubing is now crushed with the fingers or by a hemostat (Fig. 39) and the ampule filled with blood by suction owing to the release of the vacuum.

7. If blood does not flow the ampule may be rotated, in case the lumen of the needle is in contact with the inner wall of the vein. If it is apparent that

the needle is not in proper position it may be partly withdrawn and another attempt made, due care being taken not to withdraw the eye of the needle

FIG. 38.—SECURING BLOOD WITH THE COMER-KEIDEL TUBE; METHOD OF PASSING THE NEEDLE.

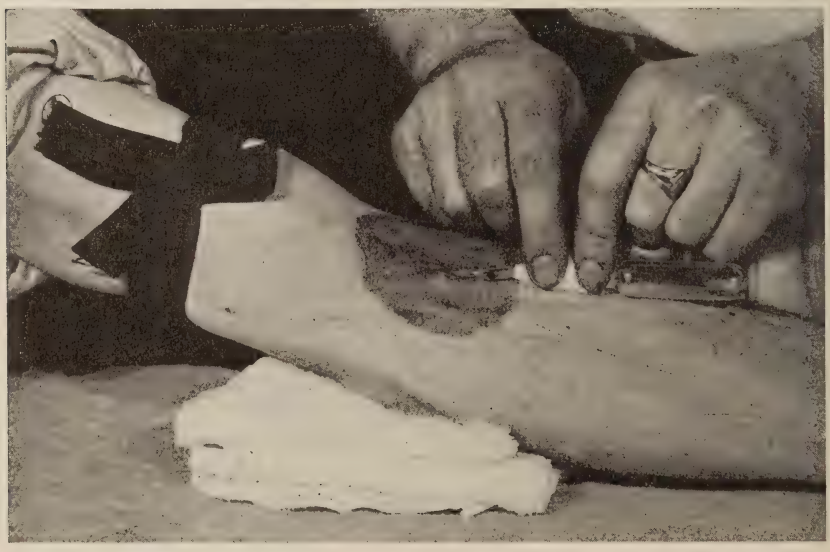

FIG. 39.—SECOND STEP IN SECURING BLOOD WITH THE COMER-KEIDEL TUBE. Blood is seen in the "window" indicating that the needle is in the lumen of the vein; the neck of the ampule is being broken to release the vacuum followed by suction of blood.

from beneath the skin, which permits the entrance of air, in case the neck of the ampule has been broken.

8. The tourniquet should be released before the needle is withdrawn to prevent subcutaneous hemorrhage.

9. The site of puncture is compressed for a few seconds and cleansed with alcohol; a dressing is not required.

10. If the blood is to be mailed it is necessary to bend down the rubber tubing and hold it in this position by a rubber band or tying with a piece of string to prevent leakage of blood or serum in transit.

With a Syringe.—Blood may be also obtained from a vein in the same manner by means of a sterilized 5 or 10 c.c. Luer or Record syringe fitted with a No. 20 to 22 needle; it is unnecessary to use a larger needle which inflicts unnecessary pain. The needle should be short and not over 1¼ inches; long needles interfere with the flow of blood and are more difficult to enter into a vein. The bevel must be short rather than long but not too

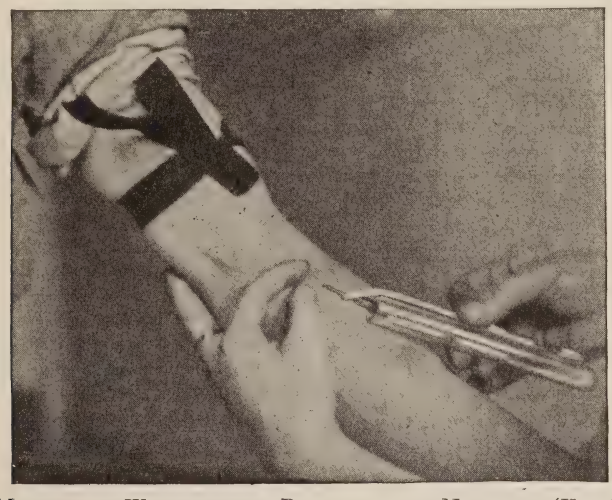

FIG. 40.—METHOD OF WITHDRAWING BLOOD WITH A NEEDLE. (Keen's Surgery.)

stumpy; it is almost imperative to use a sharp and rust-free needle to conduct the operation with the minimum of pain and without leaving a stained puncture site in the skin.

After securing the blood the tourniquet should be released before the needle is withdrawn; the blood should be emptied into a sterile test tube or better, into a small sterile vial tightly stoppered if the specimen is to be mailed. For this purpose the vial should not be of more than 10 c.c. capacity in order to reduce to a minimum the agitation and consequent hemolysis of corpuscles in transit.

The test-tube or vial need not necessarily be sterile if the blood is to be tested within forty-eight hours but if there is a longer interval, the container should be sterilized beforehand by dry heat or it may be boiled for a few minutes, drained and cooled just before use. It is imperative, however, under all circumstances, that the container shall be *chemically clean* and especially free of acids and alkalies which are hemolytic and anticomplementary.

With a Needle.—Blood may be secured from a vein by merely entering a sufficiently large sterilized needle and allowing it to flow into a prepared test-tube or vial. For this purpose the needle should be gauge 18 to 20 since suction is not applied, and the shaft should not be too long as otherwise

coagulation may occur. It is of advantage to grasp the needle with a hemostat as shown in Fig. 40. This method, however, is apt to be "messy" and is inferior to the Keidel tube and syringe methods.

By Puncture of a Finger.—From 3 to 5 c.c. of blood is readily obtained from a finger and is perfectly acceptable for the Wassermann test. In obese individuals with difficult veins or in nervous individuals who are almost sure to faint if venous puncture is attempted, this method is very valuable although it requires a little more time and patience. The technic is as follows:

1. The hand should be warm. If cold and clammy have the patient immerse the hand in hot water for a few minutes followed by brisk drying.

FIG. 41.—METHOD OF PRICKING A FINGER.

The patient's finger is grasped firmly and lanced with a Daland lancet *across the folds of the skin.* When lanced parallel with the skin-folds the wound is likely to close before sufficient blood is secured.

2. Select the middle or ring finger; cleanse with alcohol and dry.

3. Cleanse the broad blade of a Daland blood lancet with alcohol and puncture deeply across the lines of the tip of the finger (Fig. 41) with a sharp broad lancet; there is very little pain.

4. Massage the blood into a *small* test-tube or vial (Fig. 42); it is a mistake to use a large receptacle as blood is wasted on its walls.

5. Cleanse the finger and apply compression for a few seconds. A dressing is not ordinarily required unless bleeding continues.

Securing Blood from Infants and Children.—A few cubic centimeters of blood may be readily obtained from infants by puncturing one of the great toes with a Daland lancet and massaging the blood into a small test-tube, as described above for securing blood by puncture of a finger.

In the case of children from 1 to 6 years sufficient blood may be obtained by puncture of one or several fingers. In children over 6 years of age, a vein may be entered and blood drawn with a Keidel tube or syringe as above described.

Blood may be obtained with a syringe from one of the external jugular veins as shown in Fig. 43 or from a temporal vein.

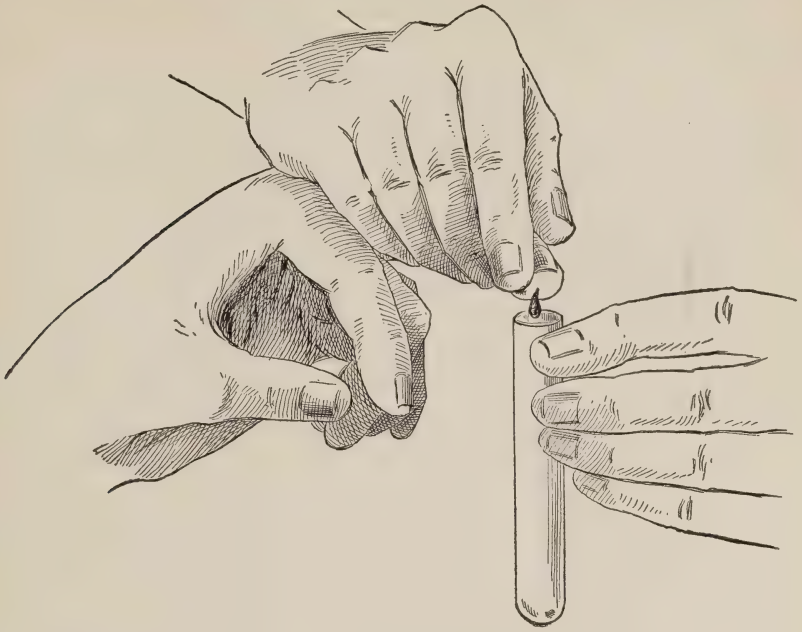

FIG. 42.—METHOD OF SECURING A SMALL AMOUNT OF HUMAN BLOOD FROM A FINGER.
By pricking the finger deeply *across* the lines of the skin with a *broad* lancet two or more cubic centimeters of blood are easily collected in a small test-tube. Do not use a large tube, as blood may be lost on the sides of the tube.

FIG. 43.—METHOD OF OBTAINING BLOOD FROM AN EXTERNAL JUGULAR VEIN.
The patient is a child six years of age; shows the position of the patient and manner of distendng the vein by pressure above the clavicle. A 5 c.c. Record syringe fitted with a No. 20 needle is being used for the withdrawal of blood. The distended vein is painted with tincture of iodin to indicate the position. (Keen's Surgery.)

Blood may be secured from infants under one year of age by puncture of the superior longitudinal sinus (Figs. 44 and 45) as follows:

1. The infant is wrapped in a blanket and the head is steadied by an assistant (Fig. 46).

2. The puncture is made on the median line of the posterior angle of the anterior fontanelle.

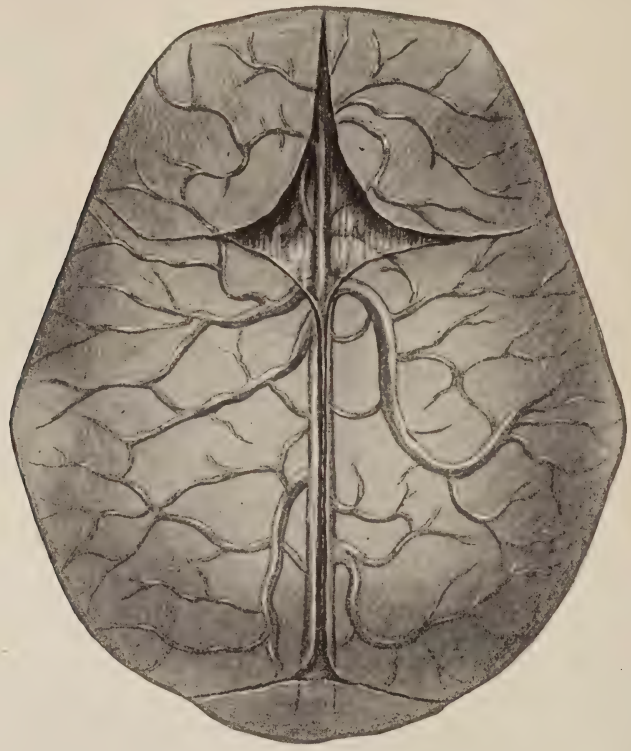

FIG. 44.—THE ANTERIOR FONTANEL AND RELATIONS AND SIZE OF THE SUPERIOR LONGITUDINAL SINUS IN A NEWBORN INFANT. (Keen's Surgery).

FIG. 45.—A CROSS-SECTION OF THE HEAD OF A NEWBORN INFANT THROUGH THE POSTERIOR ANGLE OF THE ANTERIOR FONTANEL TO SHOW THE SIZE AND SHAPE OF THE SUPERIOR LONGITUDINAL SINUS. (Keen's Surgery.)

3. The skin is carefully cleansed. The needle, gauge No. 18, with a short bevel, sterilized and attached to a sterile 5 c.c. Record or Luer syringe is

passed inward at a right angle for a distance of about 4 mm. and suction made; if blood does not flow the needle should be passed about 2 mm. further, which suffices for the majority of children up to fifteen months of age.

4. At least 3 to 5 c.c. of blood may be safely withdrawn and discharged into a vial. The puncture site is then cleansed and may be sealed with a touch of collodion.

FIG. 46.—METHOD OF OBTAINING BLOOD AND GIVING AN INTRAVENOUS INJECTION BY WAY OF THE SUPERIOR LONGITUDINAL SINUS.

The child is six months of age; the shape and size of the anterior fontanel have been outlined; a 5 c.c. syringe fitted with No. 18 needle is being employed, the needle having been entered for about 6 millimeters in the median line at the posterior angle and perpendicular to the sinus.

Methods for Obtaining Blood in Connection with Intravenous Infusions.—It is a very easy matter to obtain blood just before an intravenous injection is to be given. When administering neoarsphenamin or sulpharsphenamin with a Record or Luer syringe one may have the solution ready for injection in one syringe, but enter the needle attached to a second syringe, remove blood, *loosen the tourniquet*, deftly detach this syringe, attach the second syringe containing the solution and inject. As a general rule, coagulation will not occur before it is possible to empty the blood into a vial.

If the infusion is by gravity the same plan may be followed by entering the vein and collecting blood in a tube before attaching the tubing, releasing the tourniquet, attaching the tubing and infusing the solution. For this method however, it may be necessary to have assistance.

Not infrequently I pass the needle of a Keidel tube and fill the bulb with blood; then leaving the tube supported on the arm and before releasing the tourniquet, the needle attached to the syringe carrying the solution is entered *above*, the tourniquet released and the injection slowly given when both needles are withdrawn simultaneously. This means two punctures but the needles are small, the pain is almost neglible and both procedures are carried through without the loss of a single drop of blood.

Technic of Intravenous Infusion by Gravity Methods. *Apparatus Required.*—During the past twelve years many different kinds of apparatus and needles have been described and advocated for the intravenous infusion of dilute solutions of arsphenamin and neoarsphenamin. The simplest sort

of apparatus, however, will suffice when the technical principles are understood. That shown in Fig. 47 is sufficient if assistance is available; that shown in Fig. 48, is very satisfactory when the injections are to be given without assistance. One of the cylinders carries saline solution for the first and last part of the infusion; the second cylinder carries the solution of arsphenamin or neoarsphenamin and both are connected to the needle by a Y-glass tube or a Morton three way cock attached to six inches of rubber tubing carrying a glass window or glass adapter. The cylinders should be of at least 200 and preferably 300 c.c. capacity plainly calibrated from above downward.

FIG. 47.—METHOD OF MAKING INTRAVENOUS INJECTION BY GRAVITY.

This method is suitable for the intravenous administration of dilute solutions of arsphenamin, neoarsphenamin, sulpharsphenamin, etc. The needle has been entered into a prominent vein (indicated by a flow of blood); the tubing has been attached by means of a metal adapter which fits the needle easily and snugly; the tourniquet has been loosened and the injection is being given.

Proper care of the needles is important. They should be cleansed immediately after use, and precautions taken to prevent rust. Just before sterilization, the point should be freshened on a stone, if necessary. The bevel must not be too long, because of the danger of piercing the vein through and through or leaving the opening of the needle partly within and partly outside of the vein; neither should it be too short or stumpy. The first essential for success and a satisfied patient is the right sort of needle, bright, clean and sharp.

A piece of glass tubing, 6 mm. in diameter, should be inserted in the rubber tubing so as to be a few inches from the needle. A bulb in the tubing of ¾ inch diameter outside as shown in Fig. 49, is better than straight tubing as it permits bubbles of air to collect in the bulb, should any be present in the tubing.

The adapter at the end of the tubing must fit the needle snugly, but not too tightly, so that it may be attached or detached with the minimum of disturbance. Pinch cocks (Mohr's) are satisfactory for cutting off the flow of solutions.

Preparation of Apparatus.—As described in Chapter XLVI, toxic reactions may be produced by new rubber tubing used for the first time. It should be

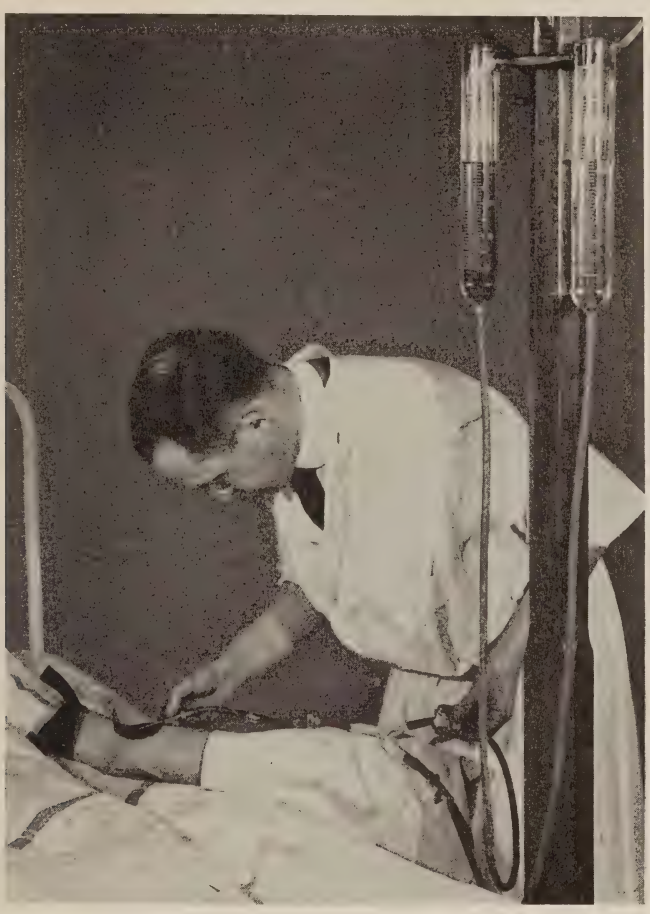

FIG. 48.—METHOD OF MAKING INTRAVENOUS INJECTION BY GRAVITY.

One cylinder carries sterile saline solution; the second carries the solution of arsphenamin or other drug to be injected. Both are connected to the needle by a Y-glass tube attached to six inches of rubber tubing carrying a glass window; pinch cocks are provided or a three way cock may be used.

soaked in normal sodium hydroxid solution (4 per cent.) for at least six hours and thoroughly rinsed in running water before sterilization.

All the apparatus, including cylinders, tubing and needles, may be sterilized by boiling for at least five minutes and cooled. Sodium carbonate should not be added to the water. Just before use the cylinders and tubing should be flushed out with sterile saline or sterile distilled water.

Everything should be in readiness, the solution of arsphenamin or neoarsphenamin being ready for infusion before the tourniquet is applied and the

needle is entered into a vein. The methods for preparing solutions are described in Chapter LXII.

Technic of Injection with One Cylinder.—The method is as follows:

1. Assemble the apparatus complete; pour in sterile saline solution (preferably at about 38°C.) and expel all air. Leave at least 30 c.c. in the cylinder; pinch off. An assistant should be available to hold the cylinder about 3 feet above the vein of the patient or the cylinder may be fastened to some support. An assistant may be required, however, to pour in the solution of arsphenamin or neoarsphenamin at the right time followed finally by more saline solution.

2. Adjust a tourniquet and prepare the skin.

3. Enter the detached needle and make sure that it is sufficiently far in the lumen of the vein with a free flow of blood. If the blood appears only in drops with a gauge 19 needle the lumen is partly obstructed.

FIG. 49.—GLASS BULB INSERTED IN RUBBER TUBING TO SERVE AS A WINDOW AND TO COLLECT BUBBLES OF AIR.

4. Deftly attach the adapter and release the pinch cock; now release the tourniquet. Watch the site of injection very carefully. There should be no pain and no swelling; the saline should flow freely.

5. An assistant should now pour the solution of arsphenamin or neoarsphenamin into the cylinder.

6. The rate of flow will be about right with tubing and a needle of the sizes advised; the flow should be even, slow and not exceeding 25 c.c. per minute. It is highly desirable, in sensitive patients, to wait a minute or two after injecting the first 10 to 20 c.c. before proceeding with the rest of the infusion.

7. As the solution reaches the 20 c.c. mark on the cylinder add about 30 c.c. more of saline and continue the infusion until the last is seen slowly passing through the glass window.

8. Pinch off the tube and quickly withdraw the needle. Cleanse the skin and seal the puncture with a bit of sterile cotton and a drop of flexible collodion.

Technic of Injection with Two Cylinders.—With this apparatus an assistant is not required and not a few patients appreciate strict privacy while undergoing treatment for syphilis.

1. In assembling the apparatus both cylinders are attached to a Y-glass tube with about 2½ feet of tubing; a pinch cock is attached to each just above the connections. The straight arm of the glass tube is then attached to about 6 inches of rubber tubing carrying a glass window and an adapter for the needle; the adapter may be of glass in which case a glass window is unnecessary. (Fig. 49.)

2. Saline solution is placed in *both* cylinders and the pinch cocks released until all air has been expelled. About 30 c.c. of saline is left in each cylinder; the arsphenamin or neoarsphenamin solution is poured in one.

3. When all is in readiness the tourniquet is applied, the skin prepared and the needle entered. When a free flow of blood is secured the adapter is deftly attached, the tourniquet released and the pinch cock released on the tubing connected with the cylinder carrying saline.

4. When it is observed that the saline flows freely with no pain or swelling about the site of puncture, the pinch cock is applied and the pinch cock connected with the tubing attached to the cylinder carrying arsphenamin solution is released.

5. The rate of flow will be about right with the tubing and needle of the sizes advised; the flow should be even and not over 25 c.c. per minute.

6. After the arsphenamin solution has disappeared from the cylinder the pinch cock should be applied and the cock to the saline carrying cylinder released for a few seconds to wash in the arsphenamin in the lower end of the tubing.

7. The tubing above the needle is now pinched, the needle quickly withdrawn, the skin cleansed and the puncture site sealed with a bit of cotton and collodion.

Technic of Intravenous Infusion by Syringe Methods. *Apparatus Required.*—Perfectly adjusted and smoothly working syringes are absolutely necessary. The Record and Luer syringes are particularly good; rubber plunger syringers are generally unsatisfactory not only because they are apt to work stiffly but because they are not easily sterilized.

My own preference is for the 20 c.c. size for routine injections of neoarsphenamin and sulpharsphenamin by way of the veins about the elbow and the 2 c.c. size for the injection of highly concentrated solutions by way of the veins on the back of the hand. A 10 c.c. size, however, can be used for both, utilizing the ampules of sterile distilled water furnished by the makers of the products, as well as for the injection of infants by way of the temporal or external jugular veins.

The needles should be gauge No. 22 with a short shaft; long shafted needles are more difficult to handle and should not be used. The needle should be bright and free of rust, very sharp and with a short bevel. It is important that the needle fit the syringe snugly so that there may be no leakage during the injection; the piston should also fit the barrel properly so that there may be no "back-firing" or sticking during the injection. It is well to assemble the syringe and needle and test it out with sterile water or saline before use. If the syringe has been used for a prior injection it should be thoroughly washed out free of all traces of blood and re-sterilized; otherwise the piston is apt to "stick."

Preparation of Apparatus.—The syringe and needle should be sterilized before use by boiling for at least five minutes; during this process the piston should be removed from the barrel to prevent cracking by too rapid expan-

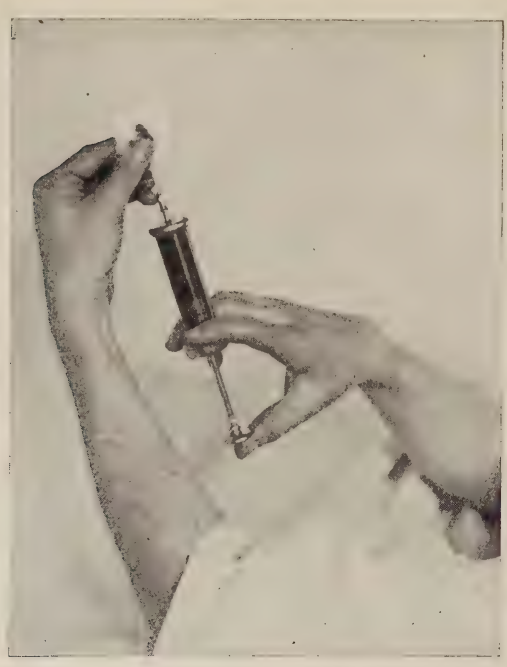

FIG. 50.—AIR BEING EXPELLED FROM A SYRINGE PREPARATORY TO INTRAVENOUS INJECTION. This is done by first attaching the needle and expelling air into a pledget of cotton carrying alcohol to collect any fluid that may be expelled.

FIG. 51.—METHOD OF MAKING INTRAVENOUS INJECTION BY MEANS OF A SYRINGE. The vein is being steadied and the needle introduced; gentle suction is then made upon the piston to determine if the needle has been properly introduced, *as shown by a flow of blood into the syringe.*

sion. It is well not to use sodium carbonate in the water; if it is used, the syringe must be thoroughly washed out with sterile water before use. The apparatus should be allowed to cool off before being loaded with the solution of medicament.

Technic of Injection.—The method of injection is as follows:

1. The syringe should be filled, the needle attached and the air expelled (Fig. 50). *The syringe should never be loaded to capacity, however, as it is necessary to give space for the "flash" of blood after the needle has been entered into the vein.*

2. When all is in readiness, the tourniquet is applied and the skin prepared; local anesthesia is not required.

3. The syringe is grasped as shown in Fig. 51; the vein is steadied and the needle entered at an acute angle to the vein.

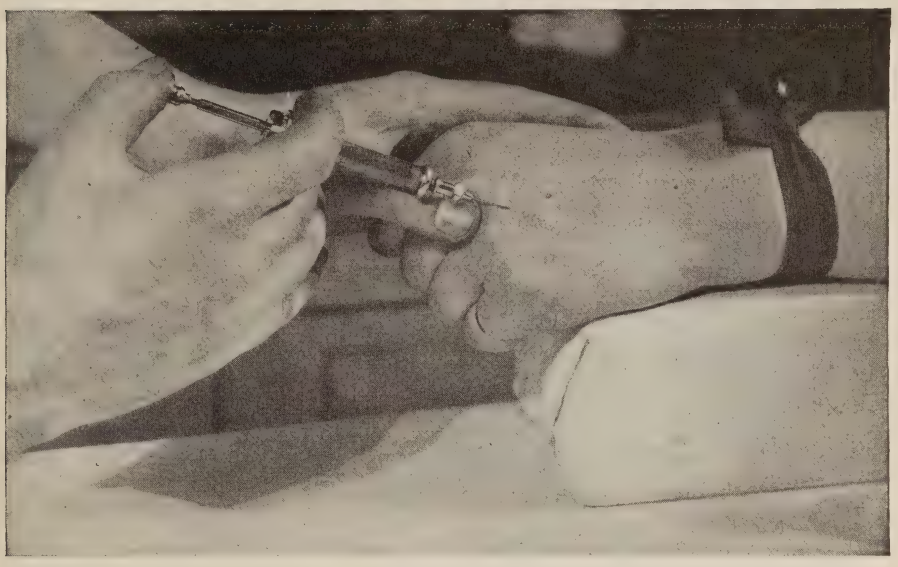

FIG. 52.—INTRAVENOUS INJECTION BY MEANS OF A VEIN ON THE BACK OF THE HAND. A tourniquet is placed about the wrist. A 2 c.c. Record syringe fitted with a No. 22 needle is being employed for injecting 0.6 gm. neoarsphenamin dissolved in 2 c.c. of sterile water.

4. When the needle has entered the vein there is a peculiar "give-away" feeling transmitted to the fingers; the syringe is now deftly grasped by the left hand and gentle suction made on the piston by the right hand.

5. A "flash" of blood is seen in the syringe. The blood should "shoot" in; if it enters slowly the lumen of the needle is not entirely in the vein. Under these circumstances it is necessary to gently rotate the syringe or to advance it a little or withdraw a little, when suction should again be made. Never inject unless the needle is surely in the vein. It is a mistake to inject and expect the patient to decide by the production of pain and swelling. If in doubt release the tourniquet and withdraw the needle. After a minute or two re-apply the tourniquet and try another vein.

6. If the "flash" is satisfactory, release the tourniquet and inject very slowly. If there is a possibility of dislocating the needle by attempts to release the tourniquet it should be left undisturbed as the injection can be

usually slowly given with the tourniquet in place. If pain or swelling are produced stop at once. After some experience has been gained one can tell by the amount of pressure required on the piston whether or not the injection is entirely intravenous.

7. The tourniquet should be released before the needle is withdrawn to prevent perivascular bleeding.

8. During all manipulations care should be taken not to touch or pierce the inside of the vein with the point of the needle, as pain is produced.

9. The position of the patient's hand for infusion by one of the veins on its back, is shown in Fig. 52.

10. The injection of infants by way of the external jugular and temporal veins is readily accomplished (Fig. 53).

FIG. 53.—METHOD FOR SECURING BLOOD AND MAKING AN INTRAVENOUS INJECTION BY MEANS OF A SUPERFICIAL TEMPORAL VEIN.

The patient is an infant 1 month of age. The head is being steadied and a vein compressed by an assistant. The injection of 0.1 gm. neoarsphenamin dissolved in 2 c.c. of sterile water is being given with a 2 c.c. Record syringe fitted with a No. 22 needle (large enough to first obtain a flow of blood before the injection is given).

11. After injection the site of puncture should be compressed and cleansed; as a rule no dressing is required but it is well to have the patient flex and extend the arm vigorously for a few seconds to make sure that bleeding will not occur before the clothing is adjusted.

12. If a 1 or 2 c.c. syringe is used it is well to use a needle of gauge No. 22; with a No. 24 or 28 needle one may not secure the "flash" of blood and dreadfully sore arms and abscesses have resulted from the injection of such highly concentrated solutions into the perivascular tissues.

CHAPTER LX

TECHNIC OF EPIFASCIAL, INTRAMUSCULAR AND SUBCUTANEOUS INJECTIONS

The technic of epifascial, intramuscular and subcutaneous injections appears to be so simple as scarcely worthy of close attention in connection with the subject of the treatment of syphilis. But in view of the fact that the bismuth salts employed in the treatment of this disease are given by intramuscular injection, as well as the growing custom of administering sulpharsphenamin by this and the subcutaneous routes, not to mention the very valuable aid given by intramuscular injections of the soluble and insoluble salts of mercury, the subject has become one of increasing importance, in which an understanding and appreciation of the anatomical considerations and niceties in technic go far toward the prevention of undue pain, tumefactions and dissatisfaction of patients.

Epifascial Versus Intramuscular Injections.—Indeed, while we commonly speak of injections into muscles as "intramuscular" this is not always the case as in some methods an attempt is made to introduce the medicament between large muscles, as between the gluteus maximus and its underlying neighbors, the gluteus minimus and external rotators, as advocated about ten years ago by Wechselmann and Eicke[1] for the comparatively painless and uncomplicated administration of arsphenamin and more recently by Stokes,[2] for the administration of mercury. It is proper to designate injections by this route as epifascial or intermuscular in contradistinction to those that are truly *intramuscular*, in which the medicament is deposited in the muscle itself.

Technic of Epifascial Injection.—According to Stokes, this is the method of choice for the injection of mercury, because it results in less pain and disability as well as fewer tumefactions. I have employed it routinely for the past several years for the injection of mercury and more recently for injections of concentrated solutions of sulpharsphenamin and neoarsphenamin; but I inject suspensions of potassium tartrobismuthate directly into the muscles themselves as bismuth compounds are less painful and less likely to result in unabsorbed tumefactions than mercury.

Anatomical Considerations.—By this method of injection an attempt is made to deposit the medicament in the areolar tissue on the upper surface of the fascia lata covering the gluteus maximus muscle. When a large volume of fluid is deposited in this region, as in the epifascial injection of arsphenamin by Wechselmann's technic, it does not form a tense induration of the body of the muscle or spread laterally to the hip or sacral margin, but presents promptly at the lower border of the buttock in the gluteal sulcus with better absorption and more freedom from local irritation than results from intramuscular injections. Due care must be taken to avoid irritation of the sciatic and branches of the superior gluteal nerves.

Apparatus Required.—A 2 c.c. Record or Luer syringe is required for the administration of mercury, bismuth and small or concentrated doses of sulpharsphenamin, neoarsphenamin and arsphenamin For larger volumes a 10 c.c. syringe may be used. It is very important, however, to use the proper

sized needles which should be of gauge 20 or 22 and 1½ inches long for thin or flabby buttocks, 2 inches for the average adult and 2½ inches for obese individuals. It is imperative that the points be rather long and very sharp; turned points are very painful. The needle should be bright and free of rust; also free of corrosion if a steel needle is employed because of the danger of the shaft snapping off in case the puncture is made with too sudden a thrust, meets with an obstruction or the patient struggles.

Preparation of the Apparatus.—The syringe and needles should be sterilized by boiling for at least 5 minutes, as due precautions must be taken against bacterial injection particularly in the injection of sulpharsphenamin and neoarsphenamin, since the resulting muscle necrosis favors bacterial activity; when mercury is being administered, bacteria are doubtless destroyed if introduced owing to the high bactericidal activity of these compounds including those that are insoluble as the salicylate, calomel and

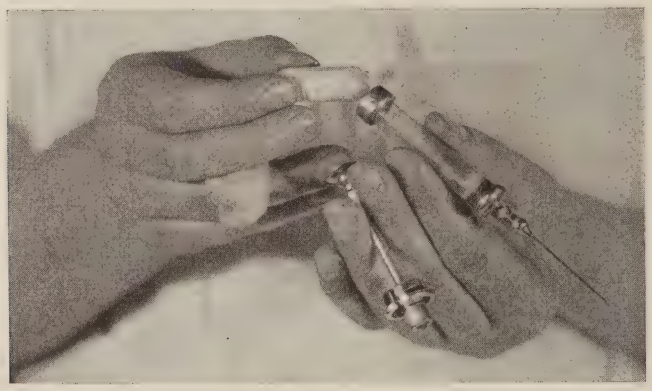

FIG. 54.—LOADING A SYRINGE WITH AN OILY SUSPENSION OF MERCURY OR BISMUTH. The ampule has been well shaken and the neck broken off. The contents are being poured into the barrel of the syringe; a 2 c.c. Record syringe is being employed.

metal itself (gray oil). Potassium tartrobismuthate suspended in oil is very much less bactericidal and due precautions against bacterial infection are required in its administration.

Loading the Syringe.—When suspensions in oil are to be injected, I believe it is a mistake to draw the suspension into the syringe through the needle to be used for making the injection, because when the needle has been entered into the tissues its lumen should be free of any obstruction to the flow of blood in case a vein has been pierced. Any one can satisfy himself that a gauge 20 or 22 needle filled with an oily suspension of the insoluble mercury and bismuth salts ordinarily employed will not readily permit the passage of blood when the syringe is disconnected or even when suction is made on the piston of a syringe loaded with 1 or 2 c.c. of the inoculum. It is a better practice to load the syringe by means of a larger bore sterile needle, as gauge No. 16 or 18, which is then disconnected.

The stock bottle or ampule of suspended drug must be thoroughly shaken before loading in order that one may obtain an even suspension and inject at least approximately the dose decided upon. In this connection I hope that the manufacturers will abandon the practice of putting up ampules with long narrow necks. Not infrequently the drug is deposited in these necks and is displaced only by the most prolonged and violent shaking. A

wide necked ampule can be opened by filling a scratch followed by a smart tap just as easily as a narrow necked ampule.

FIG. 55.—PREPARING AN AMPULE OF SULPHARSPHENAMIN OR NEOARSPHENAMIN FOR EPIFASCIAL OR INTRAMUSCULAR INJECTION.
The extreme tip of the ampule is being filed and broken off.

FIG. 56.—PREPARING A CONCENTRATED SOLUTION OF SULPHARSPHENAMIN OR NEOARSPHENAMIN FOR INTRAVENOUS OR INTRAMUSCULAR INJECTION.
With a syringe and needle about 2 c.c. of sterile water are being *rapidly* injected into an ampule of 0.6 gm. sulpharsphenamin. The ampule is now shaken to dissolve the contents.

When the medicaments as potassium tartrobismuthate, salicylate of mercury, etc., suspended in oil, are dispensed in ampules, I frequently file

off the neck, after thorough shaking and cleansing, hold a cleansed finger over the tip of the syringe (Fig. 54) and empty the oil directly into the syringe aided, if necessary, by a sweeping motion of the arm. In this way one quickly empties the *entire* contents of the ampule into the syringe which is followed

Fig. 57.—Withdrawing a Concentrated Solution of Sulpharsphenamin Prepared in the Ampule into the Syringe Preparatory to Intravenous or Intramuscular Injection.

by the introduction of the plunger, expulsion of air and the attachment of an empty needle ready for injection.

When sulpharsphenamin or neoarsphenamin dissolved in water are to be injected, the tip of the ampule may be filed off as shown in Fig. 55, and

Fig. 58.—Prone Position for Epifascial and Intramuscular Injections.

The arms are hanging over the sides of the table to promote relaxation and the toes are turned in. Showing a point (x) in the upper outer quadrant, about which *epifascial* injections may be made to advantage; the site of choice for *intramuscular* injection is shown by xx.

2 c.c. of sterile water introduced into the ampule with a syringe (Fig. 56). The contents are then dissolved, withdrawn into the syringe (Fig. 57), the air expelled and the injection given. This is a method described by Schamberg and will be referred to again with more detail in Chapter LXII.

Position of the Patient.—Epifascial injections are best given with the patient lying prone on a table and completely relaxed, the arms hanging over the sides and the toes turned in (Fig. 58) as advocated by Stokes. Rigidity and outward rotation of the toes produces dimpling of the buttocks and tends to disturb anatomical relations. Epifascial injections can be given in the standing and even in the sitting positions, but not as easily and certainly as in the prone position, although intramuscular injections are readily given in the standing or sitting positions.

Site of Injection.—The proper site is near the lower inner angle of the upper outer quadrant shown in Fig. 58. In this area one does not run the risk of striking bone or depositing the drug near large nerves with the produc-

FIG. 59.—CORRECT MANNER OF HOLDING SYRINGE FOR EPIFASCIAL AND INTRAMUSCULAR INJECTIONS WITH INDEX FINGER AGAINST THE PISTON TO PREVENT LEAKAGE.

tion of neuralgia or a persistent neuritis. It is likewise less subject to pressure upon sitting and less painful when turning in bed.

Preparation of the Skin.—The skin should be thoroughly cleansed with 1:1000 bichlorid of mercury in alcohol; 5 per cent. alcoholic solutions of iodin or picric acid may be used followed by wiping with alcohol before and after injection.

Technic of Injection.—(1) The left hand is placed flat on the buttock and with moderate pressure is drawn firmly downward toward the patient's heel, thus flattening and fixing the muscle.

(2) The syringe is grasped in the right hand somewhat like a pen with the index finger against the piston to prevent leakage from the needle (Fig. 59).

(3) The needle is introduced to its full length by a quick stroke.

(4) The syringe is now steadied by the left hand while an attempt is made to aspirate by pulling upward on the piston with the right hand (Fig. 60) to determine whether or not a vessel has been punctured by the appearance of blood (of rare occurrence).

FIG. 60.—ASPIRATION TO TEST FOR THE PRESENCE OF BLOOD BEFORE GIVING AN EPIFASCIAL OR INTRAMUSCULAR INJECTION.

FIG. 61.—TECHNIC OF INTRAMUSCULAR INJECTION.

(5) The needle is now held firmly to the syringe and steadied by the left hand while the injection is given with the right hand.

(6) When the syringe has been emptied the needle is *quickly* withdrawn and the site of injection lightly massaged with a pledget of cotton. It is unnecessary to apply a dressing.

Technic of Intramuscular Injection.—The technic of intramuscular injection is quite similar to that just described except that an attempt is made to lodge the inoculum in the midst of the muscle.

Due care must be exercised against depositing the drug in the subcutaneous tissues or in the immediate neighborhood of large nerves and particularly the sciatic and superior gluteal nerves when injections are given in the buttocks. When a series of injections are given I usually permit the patient himself to select the sites of injection and not infrequently they are able to point out exactly the area which produces least pain and disability. Injections should be given alternately in both sides of the buttocks; as a general rule injections on the left side are less painful and usually preferred.

1. The apparatus required is exactly as described above and likewise the preparation by boiling for five minutes. The needle may be gauge 20 to 22, preferably the latter, but the shaft need not be more than 1 to 1½ inches long for the average adult because the injection is to be deposited in the gluteus maximus muscle rather than beneath it, as in the epifascial injection. Due care must be exercised against the use of dull needles with turned points; also against rusty and pitted needles with partially obstructed lumens. A bright, clean, sharp needle is required for the most satisfactory results. The Rosen needle[3] is very useful for the intramuscular injection of children.

2. The syringe should be loaded in the same manner as described above; it is always important to guard against the accidental injection of a vein when administering suspensions and I believe it is well to load the syringe with a large needle (gauge 16 to 18) and replace it with the smaller empty one (gauge 20) for the injection, so that no obstruction will be offered to a flow of blood in case a vein is punctured; or the syringe may be loaded by my method shown in Fig. 54 without a needle.

3. Intramuscular injections can be made, of course, into any large muscle as the deltoid, quadriceps extensor, etc., but the gluteus maximus is the site of choice and employed in the great majority of cases because giving the least pain and disability.

4. The *site of injection* in the buttocks may be the same as described above for epifascial injection, but the majority of my patients select an area a little lower down as indicated by xx in Fig. 58. I have tried higher sites between the crest of the ileum and a horizontal line passing through the apex of the crease of the buttocks, but in my experience these injections are more painful than those given just above or just below this line. Due care should be exercised, however, against giving the injections low down near the crease because of the proximity of the sciatic nerve.

5. The patient may take a relaxed prone position on a table as described above, but the injections are given just as well in the standing position shown in Fig. 61. Injections in the sitting position are less satisfactory.

6. The skin should be wiped with bichlorid alcohol or with iodine followed by alcohol.

7. The syringe is grasped somewhat like a pen with the index finger against the piston to prevent leakage from the needle; it is my custom to slightly stretch the skin with the left hand and quickly thrust the needle into the muscle in a perpendicular position. One may readily estimate the proper depth for depositing the inoculum; care must be taken not to inject subcutaneously. The piston is now drawn backward to make suction for at least ten seconds to draw blood in case a vein has been pierced, but this is of rare occurrence. If there are no evidences of bleeding the injection is slowly given and the needle *quickly* withdrawn after the syringe has been *completely emptied.*

8. The site of injection should be briefly massaged with a pledget of cotton but a dressing is not ordinarily required.

Technic of Subcutaneous Injection.—At the present time sulpharsphenamin is frequently administered by subcutaneous injection in the treatment of syphilis; neoarsphenamin is likewise sometimes administered by this route. Arsphenamin and the soluble as well as the insoluble salts of mercury and bismuth are given intermuscularly or intramuscularly.

The technic is similar to that described above. As a general rule, it is well not to inject too concentrated solutions; for the adult patient the dose of sulpharsphenamin or neoarsphenamin should be diluted in at least 5 c.c. of sterile water, although some physicians have used 1 and 2 c.c.

A Record or Luer syringe fitted with a No. 22 needle may be employed, previously sterilized by boiling for at least five minutes.

Different *sites* may be chosen. As a rule the upper arm is unsatisfactory because of the disability resulting from the tumefaction which always follows subcutaneous injections. The skin of the abdomen below the belt line is a good location; also the skin of the chest below the inner joint of the clavicle. Injections are also given in the back below the lower angle of the scapula.

The skin should be carefully cleansed and the needle entered freely into the subcutaneous tissues. Too superficial injections are very painful. Some physicians first inject a few drops of a sterile solution of novacain, but I incorporate the anesthetic with the solution of medicament as described in Chapter LXII.

After the injection has been given the area should be well massaged; a dressing is not required.

Treatment of Complications from Epifascial, Intramuscular and Subcutaneous Injections.—For excessive pain, swelling and tenderness hot or cold applications of saturated solutions of magnesium sulphate may be used. Occasionally the pain from the injection of the arsenicals may be so severe as to require the administration of morphin. Some individuals develop unusually severe reactions from injections which the majority bear very well. The cause for this peculiar hypersusceptibility to inflammatory changes is unknown, but I suspect that it is due to some disturbance of the ferment-antiferment balance, since the injection of most anything of a bland nature is likely to elicit an excessive local reaction. A series of injections to individuals of this kind is out of the question. Possibly the hypersusceptibility is due in part to syphilitic infection, which is known to increase the sensitiveness of the skin to injections of various substances, and it may be that the simultaneous administration of the iodids intensifies the subcutaneous and intramuscular reactions, as it is known to intensify the intracutaneous reactions to "luetin," agar, and other substances.

Chronic indurations should be gently pinched and massaged by the patient; sometimes an occasional coat of tincture of iodin is of value if tenderness is present.

Abscesses are of rare occurrence. Not infrequently after injections of sulpharsphenamin and neoarsphenamin the parts appear as if an abscess were forming, but under hot or cold applications these usually subside and undergo absorption. Indeed, I believe that part of the good therapeutic effects following intramuscular and subcutaneous injections are due to the absorption of these products of tissue exudation and necrosis in the form of a non-specific protein type of therapy. Abscesses which open spontaneously or require incision should be treated in the usual manner; they are usually sterile and due precautions are required to prevent secondary bacterial infection.

If blood appears in the syringe when intermuscular and intramuscular injections are being given, the needle must be withdrawn and entered in at a new site. To inject an oily suspension under such circumstances would entail grave consequences from pulmonary and possibly cerebral embolism. I have never observed these accidents, but presume that the treatment must be symptomatic and according to circumstances, since nothing can be done for the removal of the emboli themselves.

With due care in the selection of needles and avoiding the striking of bone, the breaking of needles is a rare accident. Children, however, are risks unless their struggling from fright is restrained. When this accident occurs great presence of mind and calmness of action are required. As a general rule, the break occurs at the hub and the physician should immediately lay down the syringe and caution the patient against the slightest move while an attempt is made to pick the shaft out of the tissues. Sometimes a small incision is required. If these attempts are unsuccessful, the needle should be removed surgically with the aid of X-ray pictures for exact localization, as soon as possible and before it is massaged into the deeper tissues by muscular movements.

CHAPTER LXI

TECHNIC OF SPINAL, CISTERN AND VENTRICULAR PUNCTURE AND INJECTION

As stated in Chapter XLII, spinal puncture for the purpose of securing cerebrospinal fluid for examination is now recognized as a very important and valuable procedure for the diagnosis of symptomatic and asymptomatic infection of the central nervous system and as a guide in the treatment of all cases of syphilis. Even though there are absolutely no clinical evidences of neurosyphilis, every patient should have at least one puncture and one thorough examination of the spinal fluid before treatment is terminated in order to guard against the error of dismissing individuals as "cured" when there is present latent invasion and infection of the organs of the central nervous system. Upon this point there is a general agreement of opinion, although, as reviewed in Chapter LXXVI, there are marked differences of opinion on the question of the treatment of neurosyphilis by intraspinal treatments. Of course, the majority of patients naturally dread spinal puncture, but by proper technic the operation can be made almost painless and practically free of danger. In this chapter I shall consider the technic of spinal puncture and intraspinal injections solely from the standpoint of syphilis, without entering into a discussion of spinal puncture and intraspinal medication in other diseases of the meninges, brain or cord.

Contraindications to Spinal Puncture in Syphilis.—During the acute early stages of untreated cases of syphilis, when the spirochetes are likely to be present in the blood, spinal puncture is probably contraindicated because of the danger, theoretically at least, of favoring the localization of

the parasites in the tissues of the central nervous system. According to some investigators, when spinal puncture is performed on the lower animals with removal of a few cubic centimeters of spinal fluid at a time when bacteria are in the blood, there is the possibility of favoring infection of the meninges and it is believed, on the basis of analogy, that spinal puncture during the spirochetemic stages of syphilis may favor localization of the parasites in the organs of the central nervous system. I do not know whether this is true or not in syphilis of the human being. Insofar as experiments on rabbits with acute syphilis of the testicles and scrotum are concerned, I have never been able to show that infection of the meninges, brain and cord was favored by repeated simple punctures with the removal of small amounts of fluids, even in animals castrated after inoculation to promote dissemination of the parasites. In dogs with pneumococcus bacteremia, I have never been able to localize the organisms in the meninges by spinal puncture alone although meningitis has been favored and produced by the intraspinal injection of normal dog serum. I doubt, therefore, if simple spinal puncture with the removal of 5 c.c. of spinal fluid is actually dangerous or absolutely contraindicated during the early untreated stages of syphilis; furthermore, actual harm from such has not been observed or reported upon by numerous syphilologists who have systematically examined spinal fluid in the early stages of the disease. However, the danger of favoring localization of spirochetes in the meninges by spinal puncture during the acute early stages of syphilis when spirochetes are present in the blood by the production of vascular changes and disturbances of the choroid-meningeal plexus, *may* exist and it is well not to resort to spinal puncture at this time until after the first course of treatment which may be relied upon to rid the blood of the parasites. Furthermore, there are no practical indications for examination of the spinal fluid and intraspinal treatments at this stage of disease and in general terms it may be stated that in early syphilis spinal puncture and examination of the cerebrospinal fluid are not required until after the first six months of treatment and probably not until the end of the first year.

In the chronic stages of syphilis, spinal puncture is seldom contraindicated if care and precautions are taken against undue excitement and too great or too sudden release of spinal fluid pressure. I have observed but one fatality in my own experience that may have borne a relation to spinal puncture. This patient was an adult male with syphilis of more than twenty years' standing who developed a fatal hemorrhage in the left anterior frontal lobe of the cerebrum about eight hours after spinal puncture in bed with the removal of 4.8 c.c. of spinal fluid. The pressure was not increased and the puncture was conducted while the patient was lying on the left side without mishap and with a guage No. 19 needle which permitted the slow escape of fluid. Whether the rupture of the vessel was due to a lowering of spinal fluid pressure cannot be stated; I doubt, however, that this was the case and especially since the patient showed absolutely no signs or symptoms of reaction or distress for more than six hours after the puncture, during which time the pressure was doubtless restored to pre-puncture level. However, in cases of suspected vascular syphilis of the brain due care must be exercised in spinal puncture and since this condition may be very difficult or impossible of clinical diagnosis, I take as an indication of the possibility evidences of general advanced arterial sclerosis and chronic myocarditis with increased blood-pressure, and always insist in such cases upon the puncture being done in bed, with the patient lying upon his side and with a small calibre needle to insure a very slow rather than sudden reduction in pressure, followed by at least twenty four hours of rest in bed.

It is stated that great care is also required when a tumor in the posterior fossa is suspected. The rapid withdrawal of fluid, and especially rapid withdrawal with the patient in an upright position, may create sufficient negative pressure in the brain stem to produce hyperemia, hemorrhage and foraminal hernia, which is the engagement of the brain stem in the foramen magnum. In such cases the puncture should always be conducted with the patient lying down, with a small calibre needle to permit a very slow reduction of spinal fluid pressure and not more than 2 or 3 c.c. should be removed, followed possibly by the immediate injection of an equal amount of sterile saline solution to restore the pressure.

Dangers of Spinal Puncture in Syphilis.—Thousands of spinal punctures in cases of syphilis in all stages without mishaps have shown that this operation is safe when properly conducted. It is true that headache not infrequently follows, and likewise nausea and even vomiting in exceptional cases, due to excitement, hyperemia of the meninges, and reflex disturbances of the choroid plexus or to temporary leakage of spinal fluid into the loose epidural tissues, but these are not serious and can usually be avoided altogether by attention to certain precautions and technical details.

As stated above, spinal puncture during the acute early stages of untreated syphilis may favor localization of spirochetes in the central nervous system, but this has not been proved. After an adequate course of treatment, consisting of at least four to six intravenous injections of arsphenamin or neoarsphenamin, this danger is very probably removed and there is no evidence at all that spinal puncture, with the removal of a few cubic centimeters of fluid for laboratory examination, causes an exacerbation of neurosyphilis, although this may occur when intraspinal treatments are given.

Slight pain may be produced if a nerve filament is struck or a dull ache follow for a few hours if bone is punctured, but these cannot be listed as dangers and are of infrequent occurrence. I have never observed bacterial infection of the skin or meninges due to spinal puncture, although such have been recorded and Spiller and Payne[1] have recently described a case of idiopathic epilepsy in whom severe symptoms of meningitis with many polymorphonuclear leukocytes in the fluid appeared within a few hours and spontaneously disappeared after about twenty-four hours; this condition may have been due to infection, although very probably not from the skin, since the usual aseptic precautions were taken.

Spontaneous meningeal hemorrhage after spinal puncture has been reported and studied recently by Goldflam,[2] Meylahn[3] and Herman[4] in which the symptoms are said to have been those of a rapidly developing meningitis due to the diapedesis of blood or puncture of a vein and from which recovery may occur spontaneously in mild cases; but I have personally never seen such in many hundreds of punctures, although the appearance of a few drops of blood during the puncture as a result of piercing a vein in the passage of the needle is not of infrequent occurrence.

It cannot be stated that spinal puncture and the withdrawal of spinal fluid in syphilitics for diagnostic purposes is absolutely devoid of danger, and the operation should never be advised or undertaken hastily and haphazardly; but when the operation is properly conducted, serious accidents are quite rare and for the majority of cases of syphilis the operation may be safely and conservatively advised when the examination will be of value in diagnosis, as a guide to treatment and as a criterion of cure.

Precautions in Spinal Puncture.—Spinal puncture is somewhat more difficult when the patient is lying on his side than when in a sitting posture, but the prone position is to be preferred when the spinal fluid pressure is to be

taken and likewise when it is especially advisable or necessary to draw off the fluid very slowly. In the prone position the pressure is lower, the flow is slower, the patient more comfortable and less likely to develop faintness and nausea from fear, nervousness or sudden reduction in spinal fluid pressure. I believe it to be the position of choice for routine work, although the sitting posture is more likely to be successful and is to be preferred from this standpoint for those lacking in experience in the operation in order to minimize the possible injury to the tissues by repeated but ineffectual attempts to secure spinal fluid.

The needle should not be unnecessarily large. In syphilis the consistency of the spinal fluid is practically that of water and gauge No. 19 or even a slightly smaller needle permits the measurement of pressure and the escape of fluid. In acute suppurative meningitis, larger bore needles are required, but in syphilis it is a mistake to inflict unnecessary pain by a large needle, not to mention the greater tear in the dura and arachanoid permitting the post-puncture escape of spinal fluid into the epidural tissues which is very probably the chief cause of spinal puncture headache.

Spinal fluid should be drawn very slowly in cases of choked disc and when a tumor of the brain is suspected.

It is seldom necessary to remove more than 5 c.c. for all routine tests including total cell count, protein tests, Wassermann and colloidal gold tests. Unless the fluid is under increased pressure, it is not well to remove more than this amount except for therapeutic purposes.

Probably the most important precaution of all is rest in bed for at least eighteen hours after puncture. The chief purpose of this is to avoid spinal puncture headache. As will be discussed later with more detail, it is highly probable that this distressing after effect is due to continued leakage of spinal fluid after the needle has been withdrawn with resulting pressure upon the basilar veins and increased intracranial venous pressure and in the prone position the pressure is reduced and leakage less likely to occur than when the patient is up and about. Spinal puncture may be done in the clinic or office but I believe the patient should always be advised to return home as quickly as possible and stay on his back for at least eighteen hours; it is far better to conduct the puncture in the bedroom so that this position may be taken at once.

Technic of Spinal Puncture.—With these preliminary statements, the technic of spinal puncture may be considered and I hope the following description will be of special aid to those physicians lacking experience in this minor operation which has become an important and almost necessary part of the modern diagnosis and treatment of syphilis.

Apparatus Required and Preparation.—The *needle* should be gauge 19 to 20, free of rust, with a short bevel and very sharp (Figs. 62 and 63). Even in the hands of an expert a dull needle with a turned point inflicts unnecessary pain and not infrequently failure to secure spinal fluid. Steel needles may be employed, although some prefer platinum needles because softer and less likely to break in case of violent muscular movements by the patient. My own preference, however, is for the former and I believe it is well to discard a needle or have it sharpened after using it several times. A bright, clean, rust-free, perfectly straight, sharp needle is the first requisite for success in conducting spinal puncture and it is a mistake to use crooked, rusty, dull needles. The bevel should be short rather than long, as otherwise a portion of the fluid may be lost by leakage in the extradural tissues.

Greene[5] has recently advised the use of a gauge 23 needle with a rounded point like a cambric needle to be used with a syringe for suction, because he

has observed in experiments that this kind of needle produces the smallest tear in the dura and consequently the least chances for post-puncture drainage of spinal fluid. I have never used a needle smaller than 19–20, but am confident that this is a question of considerable importance and feel sure that it is a mistake to use the enormously sized needles and "trocars" so commonly seen in hospitals.

The needle should always be sterilized by boiling for at least five minutes and the lumen must be freely open and free of rust, coagulated blood, etc. After use, the needle should be again sterilized as spirochetes are not infre-

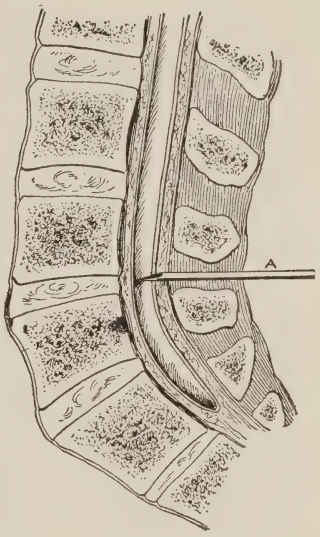

Fig. 63.

Fig. 62.—Babcock Needles for Spinal Puncture.

The needle on the left is gage No. 19 with an inside diameter of 1 mm., and is recommended for routine spinal puncture and intraspinal injections in syphilis, since the fluid is of normal consistency. The needle on the right is gage No. 15 and is recommended for spinal puncture in suppurative meningitis with thickened spinal fluid.

Fig. 63.—An Improperly Constructed Needle with the Opening so Long and Beveled that Half of the Opening May be Within the Dural Sac and Half without, Allowing Escape of Fluid into the Epidural Space. (From Frazier's Surgery of the Spine and Spinal Cord, D. Appleton and Co., New York.)

quently present in the spinal fluids of syphilitics; after drying it is well to vaselin the stylet lightly to prevent rusting.

A manometer for measuring the cerebrospinal fluid pressure is also advisable and the mercury instrument shown in Fig. 72 has been found quite satisfactory.

A sterile 1 c.c. syringe fitted with a No 26 needle is required for the intracutaneous and subcutaneous injection of sterile 1-per cent. solutions of

novacain to butyn for local anesthesia. Two sterile test tubes for the fluid, tincture of iodin, alcohol, flexible collodion and cotton completes the list of required materials.

The physician should carefully prepare the hands to guard against bacterial infection or sterilized rubber gloves may be worn. The latter also afford protection against pricking of the fingers and, since the spinal fluid may be infectious from the standpoint of the presence of spirochetes, due care

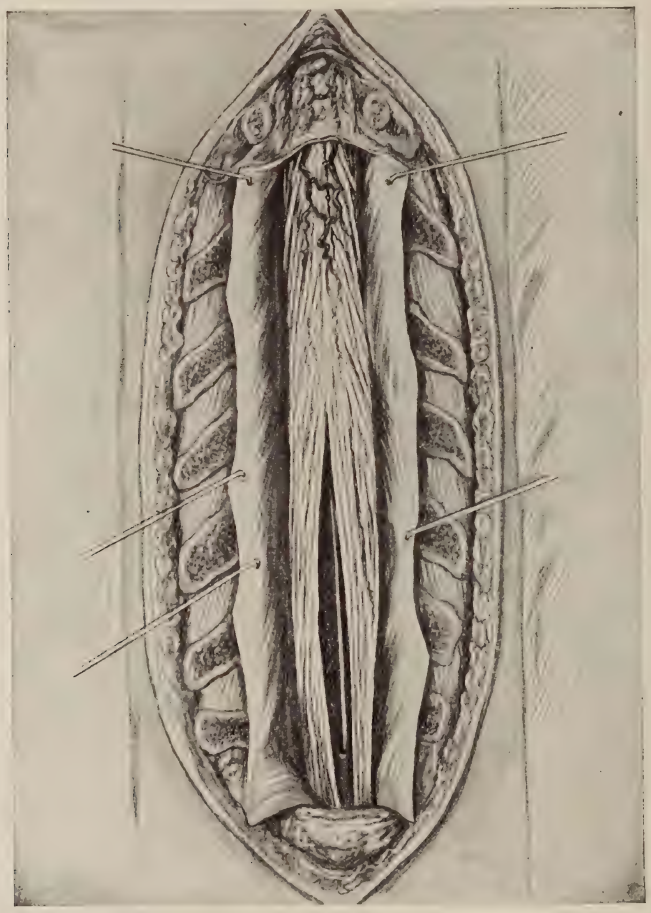

FIG. 64.—ANATOMICAL DRAWING TO REPRESENT THE SPACE BETWEEN THE BILATERAL BUNDLES OF THE CAUDA EQUINA. (From Frazier's Surgery of the Spine and Spinal Cord, D. Appleton and Co., New York.)

is required, although I do not know of any cases of syphilis caused by this means of contamination.

Preparation of the Patient.—In ambulatory patients the most suitable time for puncture is late in the afternoon to permit resting over-night. My practice is to conduct the tests whenever possible during Saturday afternoons which permits most patients to rest in bed over Sunday. It is not necessary to confine the patient for a longer period of time unless headache has followed a previous puncture, in which case a more prolonged stay is advisable.

Special preparation regarding the bowels and diet is not required, although it is well to have had the bowels evacuated and the meal preceding the puncture should be light and taken at least two hours previously. The bladder should be emptied and especially if the patient is nervous.

The skin of the back may be washed with water and soap, followed by alcohol and mercuric chlorid solution, but one or two coats of tincture of iodin followed by swabbing with alcohol just before the puncture is made are sufficient.

Site of Puncture.—Spinal puncture should always be done routinely in the lumbar region between the third and fourth or between the fourth and fifth vertebrae. The tip of the cord (conus medullaris) ends between the first and

FIG. 65.—A HORIZONTAL SECTION AT THE LEVEL OF THE FOURTH LUMBAR VERTEBRA. To illustrate the space between the bilateral bundles of the cauda equina. The lumbar puncture needle should be directed toward this space in the median line to avoid injury to the roots. (Frazier's Surgery of the Spine and Spinal Cord, D. Appleton and Co., New York.)

second lumbar vertebrae but extends a little further down in children, so that puncture between the third and fifth vertebrae will not pierce the cord.

If the patient's back is well arched, there is ample space for passage of the needle between the spinous processes of these vertebrae; it is said that in men these processes are usually directed straight backward and that the needle, therefore, may be directed straight in whereas in women of the same age and build the processes turn downward and that the needle consequently must be directed slightly upward.

Choice of Median or Lateral Routes for Puncture.—Some physicians, probably the majority, enter the needle in exactly the middle line between the vertebrae, while others prefer to enter it from one quarter to as much as one

half of an inch to the right or left of the median line directing the needle upward and inward; Regan[6] has recently reviewed the literature and opinions expressed upon this point and prefers the median route. I always use the median route, not only because it is the easier of the two but for the far more important reason, originally pointed out by Quincke himself many years ago, that the needle is less likely to strike the roots of the cauda equina, since these divide into two laterally placed bundles with a space between them of 2 to 5 mm., as shown in Figs. 64 and 65. This is a point of considerable practical importance because injury of these roots produces not only sharp pain, but has in some instances resulted in more serious motor and sensory disturbances.

When the needle is passed in exactly the middle line, the distance to be traversed before the subarachnoid space and spinal fluid are reached depends upon the age of the patient, the degree of muscular development and panniculus adiposus; in general terms, the distances are as follows, but the matter is of little practical importance, because spinal puncture cannot be performed by passing the needle an arbitrary distance:

Frail adults	4– 6 cm.
Muscular males	6– 8 cm.
Obese adults	10–12 cm.

Position of the Patient.—As previously stated, spinal puncture is easier with the patient sitting than in the prone position; this is especially true of obese individuals. When the pressure is to be taken the prone position on the left side is preferable, because the variations are less and pressures are always expressed under these conditions unless otherwise specified.

An excellent method is to have the patient sitting astride a chair facing its back with a pillow in the pit of the abdomen and the head resting on the folded arms placed on the back of the chair. The position should be perfectly straight without tilting of the pelvis and the back should be arched to give the maximum of space between the vertebral spaces (Figs. 66 and 67). The patient may also sit on the edge of a table or bed with the arms crossed and resting on the knees. If in bed, the patient should lie on either the right or left side with the thighs flexed upon the abdomen, and the shoulders and head forward (Fig. 68) in order to give the maximum arch to the lumbar region; it is very important, however, not to have the shoulders or pelvis tilting or sagging as this very materially alters the direction of the needle (Fig. 69).

Selecting the "Soft" Spot.—As stated above the proper spot for the puncture is exactly in the longitudinal middle line of the body between the third and fourth or between the fourth and fifth lumbar vertebrae. These are called the "soft" spots. By palpating the crests of the ilia and drawing an imaginary line or stretching a sterile towel between these points the "soft" spot between the fourth and fifth vertebrae may be located. As a general rule, the "spot" is just large enough to permit pressure by the index finger; the needle should be entered just a trifle below the middle of the "spot" and exactly in the middle longitudinal line.

Anesthesia.—A general anesthetic is not ordinarily required for adults unless the patient is very nervous and apprehensive when a few drops of chloroform or ether may be given principally for the psychic effect and rarely to the point of anesthesia, because local anesthesia of the skin, as about to be described, renders the operation almost painless. In tabes dorsalis and paresis the operation is peculiarly painless and even local anesthesia may be dispensed with in the case of those patients and particularly men who are not nervous or apprehensive; this always makes the puncture easier and more

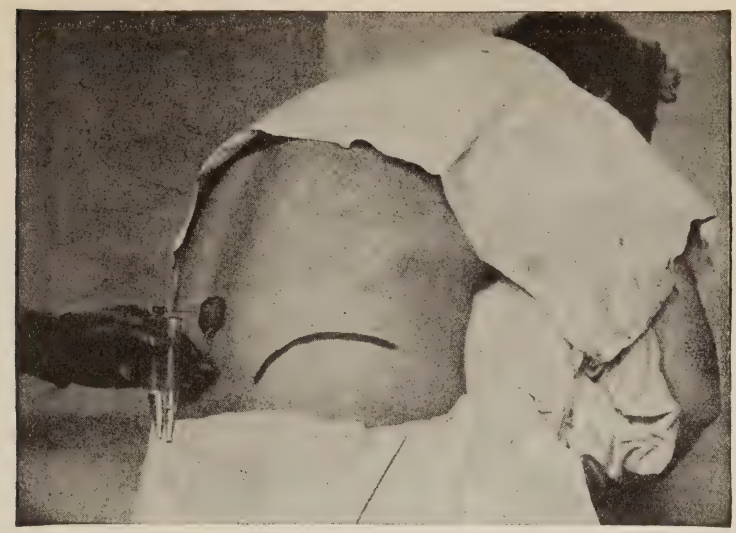

FIG. 66.—SPINAL PUNCTURE IN THE SITTING POSTURE.

The patient is an obese adult male, bent well forward over a folded pillow; the crests of the ilia are outlined. The needle has been passed between the third and fourth lumbar vertebræ in the median line; spinal fluid is being collected in sterile graduated tubes. (Keen's Surgery.)

FIG. 67.—TECHNIC OF SPINAL PUNCTURE IN THE SITTING POSITION AND BY THE MEDIAN ROUTE.

certain with the first passage of the needle, as infiltration of the skin and subcutaneous tissues with an anesthetic solution tends to obliterate the land marks and sometimes deflects the needle.

For local anesthesia a sterile 1-per cent. solution of butyn or novocain may be injected superficially in the prepared skin of the "soft spot," as shown in Fig. 70, until an elevated anemic spot is produced followed by re-entering the needle in a vertical direction in the exact middle of the spot and depositing a

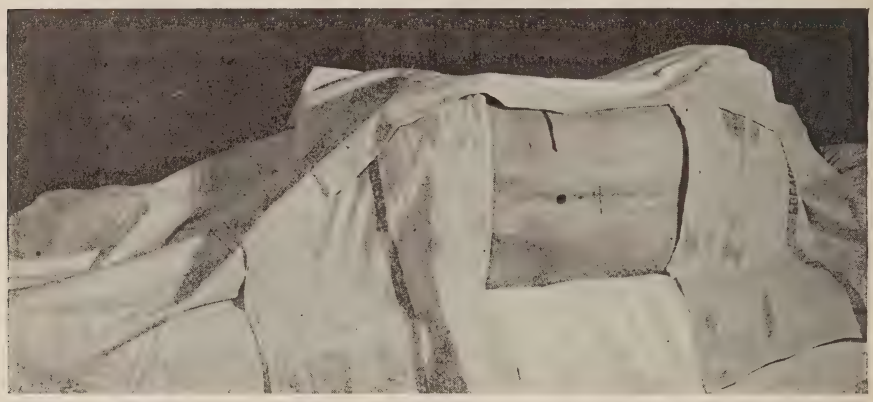

FIG. 68.—PROPER ARRANGEMENT FOR SPINAL PUNCTURE IN THE PRONE POSITION. The back is well arched and perpendicular to the table.

little of the solution as the needle is passed in to its hub. Upon withdrawal, the spinal puncture needle is entered through the same hole in the skin.

Passage of the Needle.—The spinal puncture needle is now firmly grasped about two inches from its tip and passed in exactly the middle line directly inward by gentle pressure (Fig. 71). After the skin has been passed, and with a perfectly sharp needle not larger than gauge 19 this is usually readily

FIG. 69.—IMPROPER ARRANGEMENT FOR SPINAL PUNCTURE IN THE PRONE POSITION. The back is not arched and has slumped forward.

accomplished, whereas with a dull or large needle the skin is apt to wrinkle and deviate the needle from the mid-line, the needle is gently thrust forward slowly and deliberately, rather than quickly and with great force, until it suddenly meets with increased resistance followed by a "give away" sensation which to experienced fingers indicates that the subarachnoid space has been entered. Now, but not before, the stylet may be withdrawn and fluid

FIG. 70.—METHOD OF PRODUCING LOCAL ANESTHESIA IN SPINAL PUNCTURE.

The patient is an obese adult male; the crest of right ilium is outlined and the "soft spot" between the third and fourth lumbar vertebræ located. An *intracutaneous* injection of sterile 1 per cent. butyn is being made with a 1 c.c. Record syringe fitted with a No. 26 needle. The position of the needle will then be changed to the perpendicular and the subcutaneous tissues infiltrated as far as the needle will reach. (Keen's Surgery.)

FIG. 71.—POSITION FOR HOLDING NEEDLE IN SPINAL PUNCTURE.

collected. It is my practice usually to speak to the patient during the passage of the needle in order to conduct the operation in as gentle a manner and with as little pain as possible. I have no patience with or admiration for the almost brutal and abrupt manner with which spinal puncture is frequently conducted on fully conscious, apprehensive but cowed individuals.

If the needle meets with an obstruction it should not be forced as bone has probably been met with and its injury may result in a dull aching pain. The needle should be withdrawn partly or entirely and re-passed.

Every effort should be made to pass the needle successfully with the first attempt and for this reason there should never be undue haste regardless of one's skill in conducting the operation. Every additional passage of the

FIG. 72.—MEASURING THE SPINAL FLUID PRESSURE WITH A MERCURY MANOMETER.

needle required before spinal fluid is secured only adds to the discomfort of the patient and greatly to the likelihood of post-puncture headache.

Measuring the Spinal Fluid Pressure.—The pressure should be measured before there is an escape of more than a few drops of fluid, but one must be sure that the flow is free of obstructions. The method of adjusting the instrument is shown in Fig. 72. As previously mentioned, the patient should be lying on the right or left side, breathing easily and without coughing or other muscular movements. Even a deep breath may slightly increase the pressure and violent excursions of the manometer result from coughing, change of position, etc.

The normal pressure with a mercury manometer is from 4 to 10 mm. with an average 6–8 mm.; a pressure of 12 mm. is border-line while 15 mm. or

higher is distinctly increased. In children the normal pressure is about one-third less. If the pressure is taken in millimeters of water (normal 60–120) it may be expressed in millimeters of mercury by dividing by 13.

A rough gauge of the pressure may be estimated by the rate of flow of fluid from the needle after some experience has been gained with a needle of uniform bore; at least one is able to say whether or not the fluid pressure is distinctly increased or not without being able to detect the finer differences.

The pressure is about one third higher in the sitting posture, the upper limit of normal being about 14 mm. of mercury.

Collection of Fluid.—The fluid is now collected and for this purpose two sterile test tubes should be employed. The first flow is collected in tube No. 1 as it may be blood tinged and unfit for cell counts and protein determinations but acceptable for the Wassermann test; about 2 c.c. should be collected followed by 2 c.c. in tube No. 2 (for cell counts, protein tests and colloidal gold test) and lastly by an additional 1 or 2 c.c. in tube No. 1; this gives a total of from 5 to 6 c.c. of fluid which is ample for all tests. If the fluid runs perfectly free of blood the first few drops may be discarded and about 5 c.c. collected in a single test tube or vial.

The pressure may be taken once or twice during the collection and especially in selected cases in whom a sudden or great drop in pressure is to be avoided. If headache or syncope develop the drainage should be stopped at once.

Dry Tap.—If spinal fluid fails to flow when it is believed that the needle is in the subarachnoid space, it is frequently designated as a "dry tap;" but occurring in cases of syphilis, it may be stated that almost invariably it is due to the fact that the needle is not actually in the subarachnoid space. The needle may be clogged with coagulated blood, a bit of tissue or the opening may be closed by contact with the arachnoid; it should be gently turned, pulled out or advanced very slightly. If these fail it should be withdrawn, inspected and cleaned if necessary and re-passed. In rare cases of old meningitis with adhesions or tumors obstructing the subarachnoid space, "dry tap" or a very scanty flow of fluid may occur, but in the great majority of instances, "dry taps" in syphilis are due to errors or accidents of technic.

After-treatment.—The needle should be rapidly withdrawn, the iodin thoroughly removed with alcohol and the puncture sealed with sterile cotton and collodion.

As previously stated, the patient should remain in bed for at least eighteen to twenty-four hours as originally advised by Quincke.

If the puncture is done in the clinic or office, the patient should be advised to go home immediately, lie down and retire early. As a general rule, it is permissible to get up and resume usual duties next day, but if headache develops upon arising it is usually necessary to lie down again for relief.

Spinal Puncture Headache and Other Complications.—*Soreness* of the back is frequently complained of and especially if several punctures have been made, but this effect is of little consequence and quickly passes away. Sharp *shooting pain* during the puncture is due to striking a nerve root, but is generally relieved by withdrawal of the needle and both pain and numbness quickly disappear. *Nausea, vertigo and syncope* may be due to fright, pain or in exceptional instances, to disturbances of the higher centers by alterations in the spinal fluid pressure. As a general rule, however, these quickly pass off upon the completion of the operation and are treated by the administration of a teaspoonful of aromatic spirits of ammonia in a wineglassful of cold water.

The most annoying of all complications is *headache* and it differs from all others in that, being present when the patient is sitting up, it completely

disappears when he lies down. It is throbbing and severe, and felt mostly in the frontal and occipital regions. No drugs give sufficient relief to allow the patient to walk about and attend to his affairs, or even to sit up for long periods of time, although subcutaneous injections of 1 c.c. of pituitrin have sometimes apparently afforded relief in a few of my patients. The pain comes on quickly when he arises, being fully present in a few minutes; it subsides equally fast when he lies down. In mild cases this situation persists for two or three days; in severer cases it lasts for about seven days with full severity, and then ends abruptly in the course of twenty-four hours.

The *frequency of spinal puncture headache* varies according to conditions. If the punctures are made in the office or clinic and the patients allowed to go home before going to bed, the incidence is from 40 to 50 per cent.; roughly about half of the cases develop headache. If the puncture is followed immediately by resting in bed, the incidence is not higher than 5 per cent. in my experience. Greene, who punctures with a No. 23 gauge needle, and thereby causes the minimum of injury to the membranes, states that his incidence is not higher than 4 per cent.

The *cause of spinal puncture headache* has been a subject of discussion for many years and various theories have been proposed. It has been suggested that it is due to the reduction of pressure by loss of fluid resulting in hyperemia and other changes affecting the choroid plexus, but this cannot be true in all cases, because the incidence does not bear a relation to the amount of fluid drawn and furthermore, headaches have followed in some cases when it was necessary to withdraw the needle before more than a drop or two of fluid was withdrawn. In practicing the method of spinal drainage by Dercum and Gilpin for the treatment of neurosyphilis in which 30 c.c. or more of fluid is withdrawn, I have not observed any higher incidence than in cases from whom 4 to 6 c.c. of fluid was withdrawn for diagnostic purposes, both groups being kept in bed, however, for at least eighteen hours. Nor does it appear that the stage of syphilis materially influences the incidence. It is sometimes stated that during active syphilis the incidence is lower than usual, but MacRobert[7] states that the incidence in his experience in cases of active syphilis was about 37 per cent. as compared with an incidence of 40 per cent. for the whole series.

In all probability the headache is due primarily to a leakage of spinal fluid through the hole in the dura and arachnoid into the epidural tissues, although in a few experiments on dogs I was not able to trace dyes into these tissues after lumbar punctures with gauge 18 needles. MacRobert states that, after lumbar puncture, the hole in the rigid dura is blocked by the delicate arachnoid membrane, but if it clings to the needle and is pulled into the hole forming an invagination or spout, drainage of the spinal fluid continues into the epidural tissues until the hole is healed by tissue proliferation. This results in a loss of normal water-bed support of the brain and when the patient arises the weight of the brain impinges upon the irregular bony surface of the base of the skull which alone may produce pain, but is more likely to be the result of the pressure of the brain forcing the pons on the clivus of the occipital bone, which in turn presses upon the basilar plexus of veins impeding the flow of blood about to leave the skull and forcing it to turn back and travel by other congested channels which results in congestion and a sudden rise of intracranial venous pressure responsible for the headache. When the patient lies down, the weight of the brain is removed from the veins on the clivus and congestion is relieved and in the course of a week the hole in the spinal membranes gradually heals restoring the normal water bed for the brain in the upright position.

In the *treatment of spinal puncture headache*, rest in bed gives almost immediate relief. As previously stated ordinary drugs like antipyrin, caffein, etc., are without appreciable effects. Solomon[8] believes that measures tending to raise cerebrospinal fluid pressure are indicated and observed that the intramuscular injection of 1 c.c. of pituitary extract raised cerebrospinal fluid pressure by 10 to 100 per cent. with permanent and prompt relief in some cases, temporary relief in others and no relief in a few. When the relief is temporary the injection may be repeated as required until the headache disappears spontaneously as it does in all cases. Good effects were also observed from the intravenous injections of 100 to 200 c.c. of sterile distilled water and in the treatment of severe cases it may be well to employ both procedures.

Technic of Cistern Puncture.—This refers to puncture of the cisterna magna and, while it is almost never required for the purpose of securing

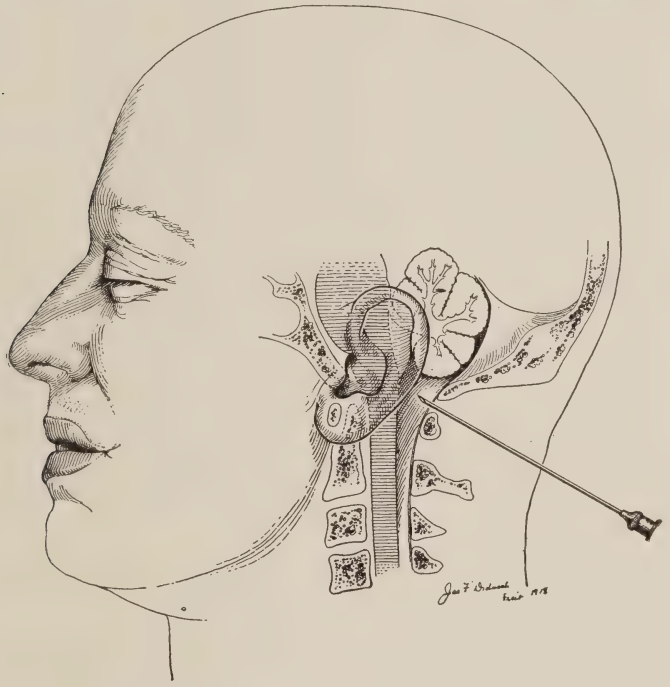

FIG. 73.—TOPOGRAPHICAL STUDY TO SHOW THE LANDMARKS USED IN PERFORMING CISTERNA PUNCTURE.

Composite prepared from numerous tracings of frozen sections. (Wegeforth, Ayer and Essick.)

spinal fluid for laboratory examinations in relation to the diagnosis of syphilis, it is worthy of more attention in relation to intraspinal medication for the treatment of severe neurosyphilis involving principally the cerebral meninges and brain as in paresis; Weigeforth, Ayer and Essick[9] have shown that injections of India ink into the lumbar subarachnoid space of cats were not distributed to these parts but greatly thinned out over the base of the brain and not visible at all over the convolutions, whereas injections into the cisterna magna filled all of the basilar cisterns and extended well over the convexity of the brain.

The anatomical relations of the cisterna magna and general direction of the needle are shown in Fig. 73, as determined by Wegeforth, Ayer and Essick in a thorough investigation of this subject. The puncture is made through the skin, subcutaneous tissues and the occipito-atlantoid ligament which stretches between the posterior rim of the foramen magnum to the corresponding position on the first cervical vertebra.

For introducing the needle a point is selected in the midline of the back of the neck just above the spine of the axis. The glabella and upper edge of the external auditory meatus are valuable for directing the course of the needle, for a line passing through them and the point of insertion on the back of the neck will pass also through the occipito-atlantoid ligament. In thin individuals, palpation over the back of the neck often reveals a deep depression between the occipital protuberance and the spine of the axis, and with the tip of the finger the approximate position of the ligament can be directly located. The distance for the needle to traverse is about 4 cm. rarely exceeding 5 cm. and never less than 3 cm. As in lumbar puncture, however, one must rely upon the tactile sense, the needle giving the same peculiar "give away" sensation when entering the cistern as when it enters the lumbar subarachnoid space.

The same kind of needle may be employed as previously described for lumbar puncture. The preparation of the patient should be the same and in syphilitic cases it is advisable to use local anesthesia as described for lumbar puncture or light ether anesthesia.

The after-treatment is exactly as described for spinal puncture and the patient should be kept in bed for at least eighteen to twenty-four hours.

Technic of Intraventricular Puncture.—Puncture of the lateral ventricles is never resorted to in syphilis merely for obtaining cerebrospinal fluid, but has been advocated as a means for the intraventricular injection of arsphenaminized or neoarsphenaminized serum in the treatment of paresis. According to Hammond and Sharpe,[10] medicaments injected intraspinally do not diffuse over the cerebrum and, even when the injections are made into the cerebral subarachnoid space, they do not diffuse to the opposite hemisphere or down the cord beyond the pons whereas injections of a dye (trypan-blue) into a lateral ventricle were found to diffuse over both hemispheres of the cerebrum, including the ventricles, and throughout the spinal subarachnoid space. From the standpoint of diffusion, therefore, intraventricular puncture is worthy of consideration, although it is questionable whether such injections are worth while in the treatment of paresis, since the spirochetes are not only in the meninges but in the substance of the brain and beyond the reach of spirocheticidal agents in the subarachnoid and ventricular fluids.

Various methods have been described for ventricular puncture, but the procedure is really a major operation, at least for the first puncture, since a small trephine of the skull is required. Under ether anesthesia, Hammond and Sharpe make an incision a little in front of the bregnia and 2.5 cm. from the sagittal sinus and remove a 1.5 cm. button of bone. The dura is incised and a slender cannula with a blunt point is introduced at a point free from cortical vessels and passed downward and a little backward into the lateral ventricle. The head of the table is lowered and from 10 to 20 c.c. of fluid collected. The table is now raised and the injection slowly given by gravity. In second and subsequent injections the scalp is infiltrated with novacain and the puncture made without general anesthesia since the brain is not sensitive.

Technic of Intraspinal Injection.—The injection of arsphenaminized, neoarsphenaminized or mercurialized serum or other substances may be made by attaching a syringe to the needle while in place and giving the injection

very slowly by gentle intermittent pressure upon the piston. For this purpose an adapter may be required for fitting the syringe to the needle being employed; the Record syringe fits the Babcock needles shown in Fig. 62 direct without adapters, and the injection may be made by means of a syringe as shown in Fig. 74.

A much better and safer procedure, however, is injection by gravity since the rate of flow and the pressure are under better control and it is possible to collect spinal fluid for admixture with the inoculum followed by injection of the whole. It is the method of choice for intraspinal, intracistern and intraventricular injections and is widely employed when such therapy is employed.

FIG. 74.—INTRASPINAL INJECTION BY MEANS OF A SYRINGE.

Apparatus Required.—It is my custom to employ a gage 19 Babcock needle for the puncture and for the injection. In addition one requires a 50 c.c. size Record or Luer syringe and about 12 inches of soft rubber tubing fitted with an adapter at one end for the tip of the syringe and a second at the opposite end for the needle (Fig. 75). A 1 c.c. syringe with a No. 26 needle may be required for anesthetizing the skin. All of these instruments are sterilized by boiling for at least five minutes so that the whole operation may be carried out with scrupulous aseptic technic.

Technic of Injection.—After the skin has been prepared and spinal puncture conducted about 5 c.c. of fluid are collected for examination. The barrel of the syringe is then attached to the needle by means of the rubber tubing and from 20 to 40 c.c. of spinal fluid allowed to collect by holding the receptacle low (Fig. 76). The serum is now poured into the barrel, mixed by gentle rotation and agitation and slowly injected (Fig. 77). If the flow is obstructed the piston of the syringe may be used for exerting gentle and cautious pressure in addition to holding the barrel as high as possible. The patient is carefully watched and pressure pains relieved by lowering the receptacle for a few seconds followed by raising it and so on until all has been

FIG. 75.—APPARATUS FOR INTRASPINAL INJECTION BY GRAVITY.

FIG. 76.—DRAINING SPINAL FLUID PREPARATORY TO ADDING SERUM FOR INTRASPINAL INJECTION.

injected. If headache or signs of respiratory or cardiac distress and syncope develop the pressure is reduced by lowering the receptacle and after a few minutes it is generally possible to continue with the injection in a slow and careful manner.

The tubing is now detached or pinched, the needle quickly withdrawn and the wound sealed with cotton and collodion.

After-treatment.—The foot of the bed should be raised and pillows removed for one or two hours in order to favor gravitation of the inoculum to the head. The patient should remain in bed for at least twenty-four hours.

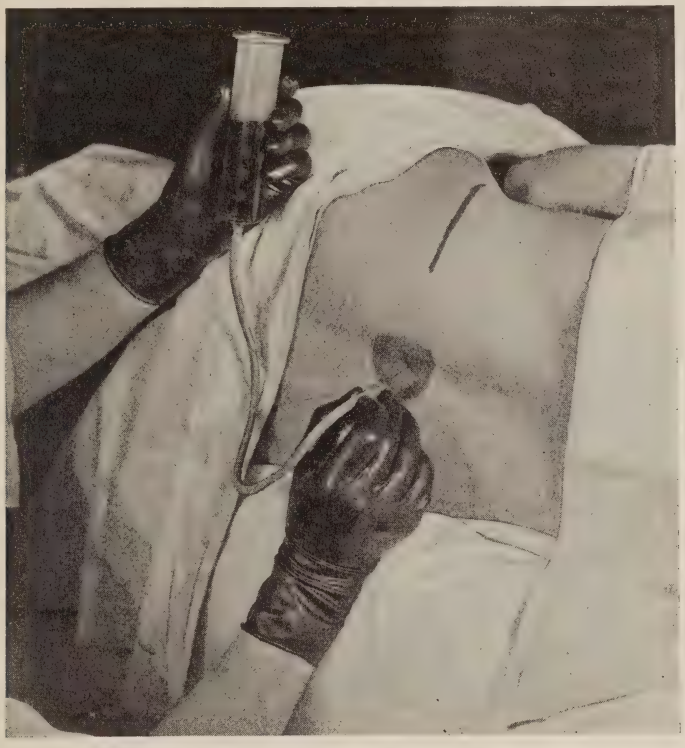

FIG. 77.—INTRASPINAL INJECTION BY GRAVITY.

Pains in the legs are generally due to pressure and tend to disappear within an hour or two. Occasionally they are severe enough to require a small dose of morphin. Headache is likewise due to pressure and may be relieved by an ice-cap.

Technic of Intracistern and Intraventricular Injections.—Exactly the same apparatus and technic may be employed for intracistern injections and, I presume, also for intraventricular injections, although I have had no experience with the latter.

CHAPTER LXII

TECHNIC OF VARIOUS METHODS FOR THE ADMINISTRATION OF ARSPHENAMIN, NEOARSPHENAMIN AND OTHER ORGANIC ARSENICAL COMPOUNDS

In the administration of arsphenamin and its substitutes, due care should be taken against those errors and faults of administration likely to produce toxic reactions. During the last twelve years various methods have been described with considerable detail so that it may appear almost unnecessary to devote much space to the subject; but there is still considerable confusion in the minds of not a few physicians called upon to administer these compounds regarding various technical points and I shall endeavor in this chapter to describe briefly methods of administration which have yielded uniformly satisfactory results and in which full cognizance is taken of the importance of the methods employed for the preparation and administration of solutions of the compounds to reduce to a minimum toxic or untoward reactions. As stated in 1922 in a bulletin issued by the Hygienic Laboratory,[1] "practically all serious reactions which have occurred in the Government services during the last five years have been especially investigated and in nearly every instance it has been shown that reactions were due (1) to some error in the technic of the preparation and administration of the drug or (2) to faulty examination of the patient, especially in relation to previous injections. In no case has it been possible to prove that the reactions have been due primarily to inherent toxicity of the drug itself."

It is well for the physician administering these compounds to become thoroughly informed upon the importance of factors relating to the drug, its administration and the patient in reference to toxic reactions as already covered in preceding chapters. In this chapter I shall endeavor to describe methods for preparing and administering arsphenamin and neoarsphenamin and other medicinal organic arsenical compounds, but the operative technic of intravenous, intramuscular, intraspinal and other injections are described in Chapters LIX, LX and LXI for the aid and benefit of those physicians giving the injections for the first time, or but occasionally, and who thereby may be lacking in experience with these methods.

General Technic. *Distillation of Water.*—All of the organic arsenicals may be given dissolved in sterile distilled water, but when arsphenamin is to be administered, I believe it is well to employ isotonic saline or glucose solutions to reduce toxicity as far as possible; these solutions, however, should be always prepared of freshly distilled water.

A supply of freshly distilled water is, therefore, one of the most troublesome features connected with the administration of these drugs in private practice. Some firms dispense ampules of distilled water for the administration of concentrated solutions of neoarsphenamin and sulpharsphenamin which are very convenient and satisfactory, since such

water will keep for a year or longer in ampules of very *hard* glass, giving off little or no alkali, as reported by Dreyfus[2] and confirmed by the widespread use of the method in this country.

Distilled water may be kept in flasks for several weeks at a time, provided they are securely sealed with gauze covered cotton stoppers against contamination. The phrase "freshly distilled" is, therefore, only of relative significance, since water distilled weeks and even months before may fulfill the requirements, provided it is stored in flasks of hard glass giving off little or no alkali and sealed against contamination.

As a general rule, physicians may secure supplies of sterile distilled water from a hospital or freshly distilled water from a pharmacy; sterilization is easily accomplished by boiling the water in the flasks or standing them in boiling water up to the level of their contents for fifteen minutes or longer. Expensive and elaborate sterilizers are unnecessary.

Most any glass or tin lined distilling apparatus may be employed providing it is kept clean and in good order; my own preference is for the Barnstead distil which is very compact, requires but little space, is easily kept clean, operates with uniform satisfaction and yields large amounts of distilled water free or almost so of organic matter. For those physicians without a supply of gas, a mo expensive type of instrument may be purchased for use with electricity.

Freshly distilled water collected in sterile flasks is ready for immediate use, but if there is any doubt of its sterility it is better to boil and cool the water before preparing solutions of the drugs. Ordinary good tap water is rendered free of all but traces of organic matter by a single distillation; if, however, the water is known to contain large amounts of organic matter, it is well to re-distil it once more or at the time of the first distillation, one may add to each quart of water a few grains of potassium permanganate which aids in the oxidation and removal of the organic matter.

Preparation of Saline Solution.—This should be prepared of freshly distilled water and chemically pure sodium chlorid; compressed tablets of sodium chlorid are sometimes unsatisfactory. Of course, the solution should be sterile and boiling for five to ten minutes is ordinarily sufficient. Experience has shown that this simple solution is just as satisfactory as Locke's or other solutions more closely approximating the inorganic composition of the blood.

An isotonic or physiological saline solution is 0.7 to 0.9 per cent., or 7 to 9 grams (average 8.5 gms.) of pure sodium chlorid per liter. For the administration of arsphenamin in dilute solution (each 0.1 gm. dissolved in 20 to 30 c.c.), a saline of this strength may be employed; when given in concentrated solution as each 0.1 gm. dissolved in 5 c.c. the saline may be one half this strength, or approximately 0.4 per cent., since each 0.1 gm. of arsphenamin in alkaline solution yields about 0.247 gm. of sodium chlorid.

When neoarsphenamin and sulpharsphenamin are given in dilute solution by gravity it is well to employ saline solution; when given in concentrated solution by a syringe (each 0.1 gm. dissolved in 3 c.c. or less), distilled water alone should be employed since enough inorganic salts are contained in the drugs to render these solutions free of hemolytic activity.

Preparation of Glucose Solution.—If solutions of glucose are employed for the intravenous administration of arsphenamin or neoarsphenamin, the usual isotonic 4.5- to 5-per cent. solutions in water are sufficient after sterilization. Higher concentrations, as up to 50 per cent., have been employed by Rubin[3] and others, but 5-per cent. solutions are sufficient for yielding the possible benefits to be derived from the administration of arsphenamin in glucose solution. It is not necessary, however, to employ glucose solutions for the immediate administration of arsphenamin and its substitutes. The influence of glucose is largely for the purpose of preventing oxidation of the compounds, but this factor is ordinarily under good control when distilled water or saline are employed.

Inspection of the Drugs.—Each ampule should be carefully inspected for cracks; if there is doubt, the ampules may be placed in alcohol for five minutes or longer and if the powder becomes moist it should not be used. This pre-

liminary immersion in alcohol also serves to cleanse the ampule and it should be subsequently laid on a sterile towel or wiped dry with sterile gauze.

Arsphenamin, neoarsphenamin or sulpharsphenamin of a dark brownish color, or otherwise varying from the usual, should not be used. The powders should also be freely movable in the ampules.

Preparation of the Patient.—The amount of preparation required or advisable depends to some extent upon the drug and route of administration to be employed. Constipation should be corrected in all cases, although severe catharsis is uncalled for and unnecessary. Arsphenamin should be administered at least three to four hours after the last meal and preferably late in the afternoon following a light lunch. Neoarsphenamin and sulpharsphenamin may be administered intravenously within a hour or two after a light meal and, when the latter is given subcutaneously or intramuscularly, no special precautions are required at all.

It is well for nervous patients dreading the injections to rest for a while before the treatment is given, and the physician should make a special effort to avoid all unnecessary display of instruments and to maintain a kind and sympathetic but firm attitude. If diarrhea is likely to follow the injection, it is well to administer 10 grains of bismuth subgallate an hour or so after the injection. If the ethereal taste is disagreeable, it is well for the patient to chew a piece of gum during and for a few minutes after injection.

Preparation of the Skin.—The skin may be prepared by applying a coat of 5-per cent. tincture of iodin followed by wiping with alcohol or by wiping with alcohol followed by 1:1000 solution of mercurophen or bichlorid of mercury. When it is necessary to expose a vein by incision, greater care should be taken in the preparation of the skin; but the above suffices for routine work when the needle is to be entered directly through the skin into a vein. With due care local infection of the site is rare and I have never observed or heard of general bacterial infections due to intravenous injections, although local infections with abscess formation have been caused by the introduction of staphylococci apparently from the skin of the patient or the fingers of the physician, following intramuscular injections of the organic arsenical and other antisyphilitic drugs.

Method of Preparation and Intravenous Administration of Dilute Solutions of Arsphenamin.—Whenever possible, arsphenamin should be administered intravenously in dilute alkaline solution by gravity injection; experience in large clinics has shown that this practice results in fewer immediate and early reactions than syringe injections of concentrated solutions.

The Solvent.—Sterile freshly distilled water, sterile physiological saline solution (0.85-per cent.) prepared of freshly distilled water or sterile 5-per cent. glucose in freshly distilled water may be employed; my own preference and practice is to employ saline solution routinely.

Dissolving the Drug.—1. For each 0.1 gm. of compound to be dissolved measure out about 10 c.c. of sterile saline solution or freshly distilled water in an Erlenmyer flask.

2. Wipe the ampule with alcohol or other disinfectant solution and open by filing the neck followed by a sharp blow; sprinkle the powder on the surface of the solvent in small amounts, then gently agitate to prevent the formation of gummy masses, until all has been completely dissolved with the minimum of shaking.

3. If the arsphenamin being employed is difficultly soluble in cold solution, the saline or water may be heated but not boiling; the powder is then added in the same manner in small amounts at a time, due care being taken against the entrance of steam into the ampule which tends to gum the contents.

A better plan with difficultly soluble arsphenamin is to pour all of the powder at once into a dry 100 c.c. glass stoppered cylinder and add 1 to 2 c.c. of pure 95-per cent. ethyl alcohol. The powder is now thoroughly moistened by means of sterile glass rod and cold saline or water added. The cylinder is stoppered and with a few shakes a perfect solution is secured. If one is sure to moisten the powder thoroughly with the alcohol (1 c.c. for 0.4 gm. or 2 c.c. for 0.6 gm.), no difficulty is experienced and this is my routine practice, although there is no evidence that hot saline or water increases the toxicity of any brands of arsphenamin being employed at present in the treatment of syphilis.

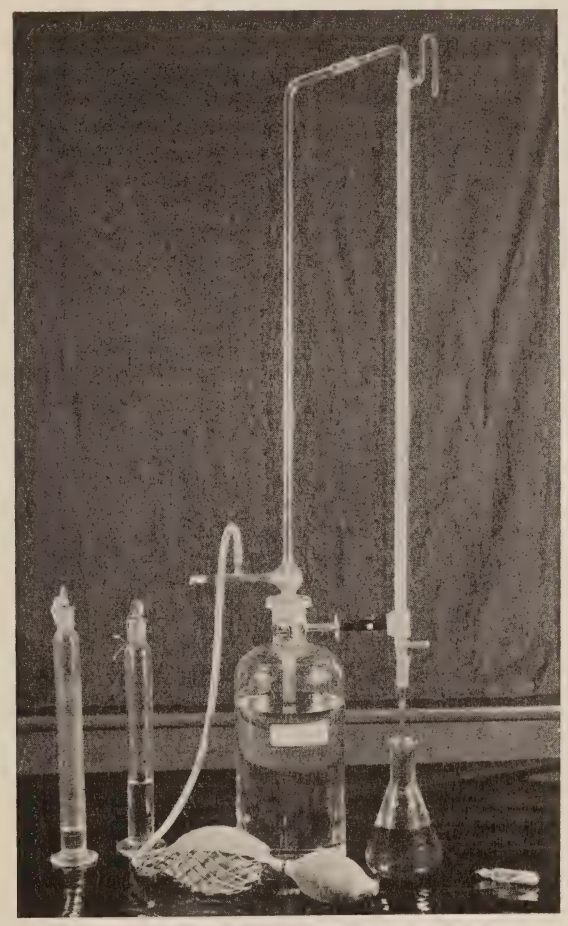

FIG. 78.—AN ALKALINIZING APPARATUS.

Alkalinizing the Solution.—When a perfectly clear solution is obtained it is ready for alkalinization. If for any reason the arsphenamin fails to form a perfect solution, it should be discarded. A clear *normal solution of sodium hydroxid* (approximately 4 per cent.) should be now added all at once in dose of 0.85 to 0.9 c.c. for each 0.1 gm. of drug; this produces a slightly alkaline solution of the disodium salt of arsphenamin which is least toxic.

A 0.4-gm. dose therefore requires 3.6 c.c. of alkali; a 0.6-gm. dose requires 5.4 c.c. The apparatus shown in Fig. 78 is very handy for keeping the

solution of sodium hydroxid free of contact with the air and for measuring it as required. The solution, however, may be kept in a bottle tightly closed with a rubber stopper to prevent the formation of sodium carbonate by the carbon dioxid of the air. The bottle, however, should be of high grade glass and one long used for this purpose; otherwise, one may take a new bottle, place in it a piece of paraffin and heat in a hot air sterilizer until the paraffin is melted. The paraffin should be then evenly distributed throughout the interior and cooled which will prevent the alkali from acting upon the glass.

As the alkali is added the solution becomes very turbid and thick followed by immediate solution with brief shaking. The solution should now be again perfectly clear, and if it is not, a few more drops of alkali may be added. If the solution is not now perfectly clear it should not be used. Excessive shaking should be particularly avoided at this time, because an alkaline solution of arsphenamin is much more readily oxidized than an acid solution.

If too much alkali has been added the solution may be brought back to the neutral point by the careful addition of normal hydrochloric acid; but great care is required and it is better in the interests of safety to discard the solution and prepare another.

Instead of the normal solution of sodium hydroxid, one may employ a 15-per cent. solution as originally advised. It is difficult, however, to know exactly just how much is required since the strength of the solution may be only approximately correct, but small measured amounts may be carefully added until the precipitate has been formed and re-dissolved. When the point of a perfectly clear solution has been reached, one should add one third more of the alkali to the clear solution to produce the disodium salt. As a general rule, the following amounts of 15-per cent. sodium hydroxid are required for this purpose:

0.2 gm. arsphenamin requires 0.5 c.c. or 11 drops of 15 per cent.
0.3 gm. of arsphenamin requires 0.7 c.c. or 16 drops of 15 per cent.
0.4 gm. arsphenamin requires 1.0 c.c. or 20 drops of 15 per cent.
0.5 gm. arsphenamin requires 1.3 c.c. or 25 drops of 15 per cent.
0.6 gm. arsphenamin requires 1.5 c.c. or 32 drops of 15 per cent.

It is to be understood that the amounts of 15-per cent. sodium hydroxid here given are for the purpose of adding approximately one-third excess; therefore, about one third less than the amounts given is sufficient for producing the precipitate followed by clearing and the production thereby of a solution which is mainly one of the monosodium salts of arsphenamin.

Diluting the Solution.—Each 0.1 gm. of arsphenamin should be dissolved at least in 20 c.c. of saline solution or water so that a 0.4 gm. dose requires 80 c.c. and a 0.6 gm. dose 120 c.c. The drug may be dissolved and alkalinized in less saline or water, but should be diluted before administration as the incidence of reactions is diminished by the slow injection of dilute solutions.

Standing to Decrease Toxicity.—The alkalinized solution should now be left standing in a stoppered flask or cylinder for 30 minutes before injection in order to reduce its toxicity. The solution may stand as long as three hours without undergoing any increase in toxicity, providing it is protected from the air, not shaken and the temperature does not exceed 30°C.

Filtration and Administration.—The solution should now be filtered either into a second sterile flask or into the cylinder employed for administration. One may use sterile filter paper, a small wad of sterile cotton or several layers of sterile gauze. This step is always advisable for the purpose of removing minute particles of glass or other foreign material.

The injection apparatus should be sterile and preferably rinsed out with sterile distilled water just before use. The technic of injection is described on page 827. The patient should be lying on a table or bed and the rate of injection should not exceed 25 c.c. per minute so that a 0.4-gm. dose requires a minimum of four minutes for injection and preferably five minutes.

After Care of the Patient.—The site of puncture should be wiped with alcohol or antiseptic solution and sealed with flexible collodion. The patient should rest under observation for at least an hour and preferably several hours eating lightly or not at all for at least four hours and avoiding active movement or excitement.

Method of Preparation and Intravenous Administration of Concentrated Solutions of Arsphenamin.—When the dose to be administered is less than

FIG. 79.—SUITABLE METHOD FOR FILTERING CONCENTRATED SOLUTIONS OF ARSPHENAMIN, NEOARSPHENAMIN AND SULPHARSPHENAMIN.

The vial (on extreme right) measure 90 × 35 cm., is plugged with cotton and sterilized beforehand. The small glass funnel is fitted with a folded filter paper, wrapped in a piece of newspaper and sterilized beforehand by dry heat.

0.4 gm., this method may be employed, although as previously stated the injection of dilute solutions is always to be preferred:

Examine the ampule carefully, cleanse, open and:

1. Empty the contents (0.1 to 0.3 gm.) into a sterile 25 c.c. graduated cylinder.
2. Add 1 c.c. of pure ethyl alcohol and thoroughly moisten all of the powder.
3. Add 20 c.c. of cold or warm sterile water or saline solution, place the stopper and dissolve the drug with the minimum of shaking.
4. *For each* 0.1 *gm. of arsphenamin* add 0.9 c.c. of normal (4 per cent.) solution of sodium hydroxid or 0.25 c.c. of a 15-per cent. solution, using a graduated 1 c.c. pipet.

5. Mix gently; the solution should be perfectly clear. Filter through paper into a sterile vial (Fig. 79).

6. Draw the solution into a sterilized Record or Luer syringe, adjust a No. 22 needle and inject very slowly, using the technic described on page 831. The patient should be preferably lying on a table or bed although injections may be given in the sitting position.

An ampule of 0.4 or 0.6 gm. of arsphenamin may be prepared in this manner with a larger cylinder and by noting in the cylinder the total amount of solution one may inject with the graduate syringe an amount of solution corresponding to the dose which it is desired to administer.

7. The site of puncture usually requires no further attention than briet compression or covering with collodion. The patient should rest under observation for at least one hour and preferably several hours.

Method of Preparation and Intravenous Administration of Dilute Solutions of Neoarsphenamin.—Since most brands of neoarsphenamin now available are of very low toxicity, this method is gradually falling into disuse in favor of the method of concentrated solutions administered intravenously by syringe injection. It cannot be denied, however, that fewer reactions follow the injection of dilute solutions of gravity than syringe injections of concentrated solutions and in large clinics it is frequently possible to give the gravity injections as quickly as by syringe by having one operator handle two tables. the technic is as follows:

1. Examine the ampule carefully, cleanse, open and empty the contents into a sterile graduated cylinder and add at least 10 to 15 c.c. of sterile cold saline solution or water for each 0.1 gm.; or the drug may be emptied into a sterile Erlenmeyer flask and the solution added, although the former method is preferable.

Careful inspection of the drug is even more important than in the case of arsphenamin since the drug decomposes more readily even though there are no cracks in the ampule. The powder should be freely mobile and lemon-yellow to canary-yellow in color. When it approaches a red color, is distinctly lumpy or solidified, it should not be used.

2. Adjust the stopper and dissolve the drug with a minimum of shaking.

3. *Do not use if the solution is not perfectly clear.* Alkalinization is not required.

4. Filter through sterile paper, cotton or gauze to remove foreign matter if present.

5. Inject immediately; it should not be allowed to stand at all, as in the case of solutions of arsphenamin, or never over 20 minutes. For this reason it is well to prepare no more solution than can be administered in this time. The rate of injection should not exceed 25 c.c. per minute; the technic is described on page 827. The patient should be lying on a table or bed and should rest under observation for at least one half to an hour.

Method of Preparation and Intravenous Administration of Concentrated Solutions of Neoarsphenamin and Sulpharsphenamin (First Method).—I have found the following method very satisfactory for the routine intravenous administration of neoarsphenamin and sulpharsphenamin in concentrated solutions and especially for office administration:

1. Carefully inspect the ampule to guard against the mistake of injecting arsphenamin; also for cracks and for changes in the color and mobility of the contents as described above.

2. Cleanse the ampule, open and pour the contents into a sterile graduated glass stoppered 25 c.c. cylinder.

3. Add 20 c.c. of sterile distilled water, stopper and shake briefly to secure a perfect solution.

4. Do not use if the solution is not perfectly clear.

5. Filter through sterile paper into a sterile vial (see Fig. 79).

6. Draw the solution into a sterile 20 or 30 c.c. syringe and inject at once through a No. 22 needle, as described on page 831.

7. The patient may be sitting up with the arm extended. As a general rule, the patient may depart at once and engage in usual activities unless a reaction develops which is of uncommon occurrence with the better brands of both drugs.

Method of Preparation and Intravenous Administration of Concentrated Solutions of Neoarsphenamin and Sulpharsphenamin (Second Method).—The following method devised after that described by Schamberg[4] is likewise very serviceable and may be employed with the sterile distilled water furnished by manufacturers of the compounds:

1. Carefully inspect the ampule and file off the extreme tip to give an opening just large enough for the introduction of a needle.
2. Cleanse and open an ampule of water and draw the contents (usually 5 to 10 c.c.) into a sterile 10 c.c. syringe fitted with a large needle (or the injecting gage No. 22 needle may be used).
3. Expel a few cubic centimeters of water into the ampule of drug rather forcibly; close the opening with a cleansed finger and shake briefly until all has been dissolved.
4. Do not use solutions unless perfectly clear.
5. Draw the solution back into the syringe and mix with the balance of the water.

FIG. 80.—ATTACHMENT FOR FILTERING CONCENTRATED SOLUTIONS OF NEOARSPHENAMIN OR SULPHARSPHENAMIN DURING THE INJECTION.

6. Expel the air and inject intravenously at once. By means of a filter attachment (Fig. 80) the solution may be filtered either while loading the syringe or during injection (former preferred), although this is not absolutely necessary if the solution is perfectly clear.
7. The patient may be sitting with the arm extended as described on page 831. The rate of injection should not be faster than one minute by the watch.
8. As a general rule the patient may go at once and resume usual activities unless a reaction occurs which is rare with the better brands of both compounds.
9. A still more concentrated solution may be obtained by placing 1 or 2 c.c. of sterile distilled water in an ampule as described, dissolving and injecting with a sterile 1 or 2 c.c. syringe fitted with a No. 22 to 26 needle. Even 0.9 gm. of neoarsphenamin or 0.6 gm. of sulpharsphenamin may be administered in this manner and especially when it is necessary to use a vein on the back of the hand, although the more dilute solutions are to be preferred.

Method of Preparation and Intravenous Administration of Silver Arsphenamin.—This compound is really silver sodium arsphenamin which yields a neutral solution and therefore does not require neutralization. *Silver neoarsphenamin* is also employed abroad; both are administered in exactly the same manner as follows:

1. Inspect the ampule, cleanse, open and discharge the contents into a sterile 100 c.c. graduated cylinder.
2. For each 0.1 gm. add 10 c.c. of sterile distilled water or saline solution and dissolve with the minimum of shaking. Do not add alkali.

3. Filter and inject at once. If the dose is not more than 0.2 gm. the injection may be given with a syringe; larger doses should be diluted with saline so that each 0.1 gm. is contained in 20 c.c. and injected by gravity. It is possible, however, to give 0.3 gm. dissolved in 20 to 30 c.c. of saline or water by syringe injection and especially silver neoarsphenamin.

4. The rate of injection should be very slow by either method.

5. The patient should be under observation for at least an hour and should rest quietly for the following few hours.

Method of Preparation and Intravenous Administration of Sodium Arsphenamin.—This compound is not being widely employed at present, but may be administered in either dilute or concentrated solutions in exactly the same manner as neoarsphenamin. Solutions are prepared exactly as described for neoarsphenamin; gravity injection of dilute solutions yields fewer reactions and is to be preferred.

Method of Preparation and Intravenous Administration of Tryparsamid. This substance is usually administered in concentrated solution after the same manner as neoarsphenamin, as follows:

1. Cleanse the ampule, open and discharge the contents in a sterile 25 c.c. graduated cylinder (adult dose usually 1.5 to 3 gm.).

2. Add 10 to 20 c.c. of sterile distilled water or saline and dissolve.

3. Filter and inject intravenously with a syringe fitted with a No. 22 needle as described on page 831. Or the solution may be taken into the syringe and filtered as injected by means of the filter attachment shown in Fig. 80. The rate of injection should be slow, at least one or two minutes being taken.

4. The injection may be given with the patient sitting and usually no immediate toxic reactions are produced.

Sutton Method of Preparation and Intramuscular Administration of Arsphenamin.—Various methods have been advocated for the intramuscular injection of arsphenamin since first introduced by Ehrlich about fourteen years ago, but this route has been largely abandoned within recent years because of the severe local reactions. Sutton, however,[5] has recently described the following technic:

1. Dissolve the arsphenamin in 6 c.c. of sterile water by the aid of rough-surfaced glass beads.

2. Add 4 drops of a 1-per cent. alcoholic solution of phenolphthalein as an indicator.

3. Add a freshly boiled 4 per cent. solution of sodium hydrate, drop by drop with a pipet, meantime gently agitating the mixture, until the resulting emulsion is slightly, but permanently pink in color. Sutton states that it is better not to carry alkalinization too far, as it does not increase therapeutic activity and tends to render the drug more irritating to the tissues.

4. The mixture is then drawn into a sterile syringe, to which is attached a needle at least 2 inches long and injected into the gluteal muscles, care being taken to place it in the middle of the muscle mass. The technic of intramuscular injections is described on page 841.

5. The injections are repeated once every four weeks, four injections forming a series.

6. In making injections by this method I have found that the addition of 2 c.c. of a sterile 2-per cent. solution of butyn to the solution greatly aids in reducing the degree of immediate pain.

Method of Preparation and Intramuscular Administration of Neoarsphenamin.—Neoarsphenamin produces less local irritation than arsphenamin and especially when the solutions are neutral in reaction rather than alkaline. Multiple small doses may be given to infants and children with very satisfactory results and with but slight local reactions. Larger doses in adults invariably produce local reactions of varying severity although the immediate pain may be controlled by incorporating a local anesthetic. The solutions should be concentrated and injected into a large muscle as the gluteus maximum with a sharp needle, rather than in the fascia. The following methods may be employed:

For Infants.—Select an ampule containing 0.1 or 0.2 gm. Inspect carefully, cleanse with alcohol and file off the extreme tip. With a sterile graduated 1- or 2-c.c. syringe fitted with a long, gauge No. 20 or 22 needle, transfer to the ampule 1 c.c. of sterile distilled water for each 0.1 gm. of drug and dissolve. Draw the solution back into the syringe; each 0.1 c.c. contains 0.01 gm. of drug so that a dose of 0.05 gm. requires the injection of 0.5 c.c.; a dose of 0.07 gm. requires 0.7 c.c., etc. Filtration is not necessary. Inject deeply into the gluteal muscles; the Rosen needle is recommended for this purpose, but ordinary gauge No. 20 or 22 needles at least one to two inches in length, depending upon the size of the patient, are satisfactory, due care being taken to prevent excessive struggling.

For Older Children and Adults.—Select an ampule containing 0.6 gm.; inspect carefully, cleanse with alcohol and file off the extreme tip. With a 2-c.c. graduated syringe fitted with a long (1½ to 2 inch) gage No. 20 or 22 needle, very sharp, transfer to the ampule 2 c.c. of a sterile 1 per cent. solution of butyn in water or 2 c.c. of a sterile 2-per cent. solution of stovain in water. Dissolve with the minimum of shaking and draw the solution back into the syringe. Filtration is not necessary. Inject into the gluteal muscles as described on page 841. A dose of 0.9 gm. may be given in the same manner or better by dissolving in 3 c.c. of the anesthetic solution.

The stock anesthetic solution may be kept in a sterile well stoppered Erlenmeyer flask or bottle and it is my practice to add 0.3 c.c. of pure phenol to each 100 c.c. as a guard against contamination.

Very careful aseptic precautions are required to prevent local infection.

Methods of Preparation, Intramuscular and Subcutaneous Administration of Sulpharsphenamin.—Sulpharsphenamin produces less local reaction than either arsphenamin or neoarsphenamin, but is also less therapeutically active in the treatment of syphilis. Intramuscular injections of concentrated solutions are usually less painful than subcutaneous injections. Intramuscular injections are best given in the buttocks, as described on page 841; subcutaneous injections may be given under the skin of the abdomen (above or below the belt line), under the skin of the thorax near the inner end of the clavicle or at the lower angle of the scapula (least desirable because frequently interfering with sleeping on the back). Very careful aseptic precautions are required to prevent infection.

For Infants.—The technic is exactly as described above for the intramuscular injection of neoarsphenamin.

For Older Children and Adults.—The technic is exactly the same as described above for the administration of neoarsphenamin although plain sterile distilled water may be employed instead of the solutions of butyn or stovain. The usual dose is from 0.4 to 0.6 gm.; the former may be dissolved in 1 c.c. and the latter in 2 c.c. giving approximately 30 to 40 per cent. solutions. More dilute solutions may be employed as 0.4 to 0.6 gm. dissolved in 5 c.c. of sterile water, but I believe there is less irritation and discomfort from the more concentrated solutions and especially when administered in 1 to 2 c.c. of sterile 1-per cent. solutions of butyn preserved with 0.3-per cent. phenol, as described above for the intramuscular injections of neoarsphenamin.

Method of Intraperitoneal Administration of Neoarsphenamin.—Since intraperitoneal injections of physiological saline, glucose and sodium bicarbonate solutions and blood have proven useful in the treatment of the diarrheas, acidoses and other diseases of infants, Rosenberg[6] has studied the effects of intraperitoneal injections of neoarsphenamin in rabbits and has given one infant repeated injections with apparent success. I have had no experience with the method, but it is worthy of consideration when intravenous injections cannot be given, although I believe intramuscular injections should yield just as good results with probably less pain. Sanford[64] has

recently reported the successful use of the method in the treatment of ten cases, the usual dose per ten pounds of weight being 5 c.c. of a solution prepared by dissolving 0.15 gm. in 15 c.c. of warm sterile water, every three days for four injections followed by four more at seven day intervals.

Swift-Ellis Method of Intraspinal Administration.—According to Fordyce,[7] the original technic of Swift and Ellis produces least irritation of the lower portion of the spinal cord and is the method of choice; the technic is as follows:

1. Inject intravenously 0.6 gm. of arsphenamin in alkaline solution (disodium salt) as described on page 827.
2. One half hour later remove 40 to 50 c.c. of blood aseptically from a vein of the same or opposite arm; the technic is described in Chapter LIX.
3. Place the blood in a refrigerator over night.
4. Centrifuge and carefully transfer the serum with a sterile pipet to another sterile centrifuge tube and centrifuge again to secure serum free of corpuscles.
5. Pipet the serum to another sterile tube and heat in a water bath for one half hour at a temperature of 56°C.
6. Conduct spinal puncture with the patient on his side and remove about 5 c.c. of fluid for examination. Then attach gravity apparatus and allow 30 to 40 c.c. of spinal fluid to accumulate in the receptacle. Add the heated serum and allow the mixture to slowly re-enter the subarachnoid space by gravity as described on page 858.
7. If neoarsphenamin is injected intravenously instead of arsphenamin, in order to reduce the chances of producing an early toxic reaction, the dose should be 0.9 gm. unless contra-indicated. The intravenous injection may be made by the syringe method. Better results, however, have been observed with intravenous injections of dilute solutions of arsphenamin as described above.
8. The puncture site should be cleansed and sealed with collodion. The patient should remain in bed for at least eighteen to twenty-four hours and longer if a reaction results. For the treatment of untoward effects see Chapter LXI.

Ogilvie Method of Intraspinal Administration.—In this method arsphenamin is not injected intravenously but sterile human serum is arsphenamized *in vitro* according to the following technic, and injected intraspinally:

1. Place 10 c.c. of sterile *clear* human serum in a sterile test-tube in a water bath at 37°C. The serum may be autogenous or that from another individual may be used. It must be sterile, free of corpuscles by one or two centrifugings and likewise free of hemolyzed erythrocytes.
2. In a sterile 100 c.c. glass-stoppered graduated cylinder place 0.1 gm. of arsphenamin. Add 99 c.c. of sterile distilled water at 38°C. and dissolve. Add 0.9 c.c. of *normal* sodium hydroxid and mix gently. The solution is now faintly alkaline and each cubic centimeter contains 0.001 gm. (1 mg.) of arsphenamin.
3. With a sterile 1 c.c. pipet add 0.2 to 0.5 c.c. of arsphenamin solution to the serum and mix. Each 0.1 c.c. of solution carries 0.1 mg. of arsphenamin; the maximum dose is 0.5 mg. of arsphenamin or 0.5 c.c. of the solution.
4. Keep the mixture in a water bath at 37.5°C. for 45 minutes; then place in a thermostat or water-bath at 56°C. for an additional thirty minutes.
5. Inject intraspinally within an hour; under no circumstances inject if more than three hours old from the time it is removed from the last heating.
6. Conduct spinal puncture with the patient on his side. Remove 15 c.c. of spinal fluid (20 c.c. if the pressure is increased). Attach the gravity apparatus (see page 858) and allow 10 c.c. of fluid to accumulate in the receptacle; pour in the arsphenamized serum and slowly inject into the subarachnoid space.
7. The puncture site should be cleansed, sealed with collodion and the patient kept in bed for at least eighteen to twenty-four hours and longer if a reaction (for treatment see Chapter LXI) develops.

Author's Method of Intraspinal Administration.—In 1920 I described a method of intraspinal treatment of selected cases of neurosyphilis[8] which permitted the treatment to be given in a few hours and combining the effects of intravenous medication, as in the Swift-Ellis method, along with the principle of arsphenamizing the serum *in vitro* before intraspinal injection, as in the Ogilvie method.

Unquestionably the Ogilvie method in my experience produces a higher incidence of lower cord irritations than the Swift-Ellis method and the same may be said of my own method, but during the past year and a half I have substituted the use of neoarsphenamin, since the brand I have employed possessed almost the same curative activity as arsphenamin with a much lower toxicity, along with the use of only one-fourth as much sodium citrate, the omission of spinal drainage and the thorough mixing of the neoarsphenamized serum with spinal fluid before injection with the result that the intraspinal injections are as well borne as in the Swift-Ellis method. Furthermore, since using neoarsphenamin general reactions from the intravenous injection are almost unknown, whereas when arsphenamin was injected intravenously it was not unusual for the patient to develop fever, chilliness, etc., which rendered him unfit for the intraspinal treatment. The technic of my modified method is as follows:

1. 0.9 gm. of neoarsphenamin is dissolved in exactly 18 c.c. of sterile distilled water and filtered.

2. One cubic centimeter of this solution is removed to a sterile tube and the balance is injected intravenously with a syringe.

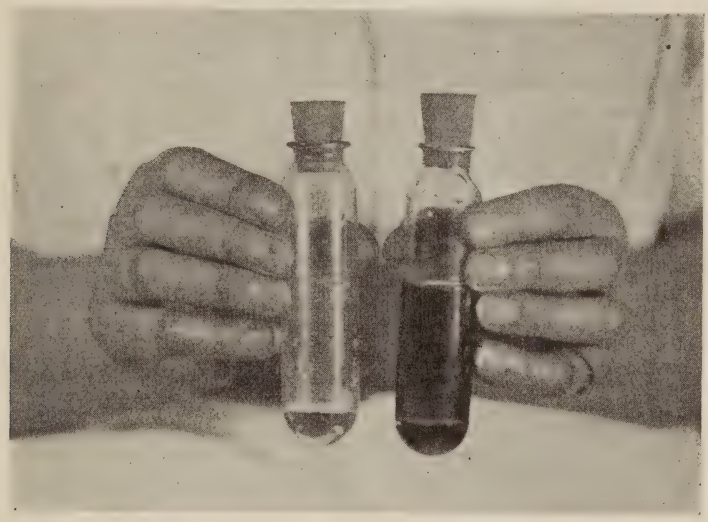

FIG. 81.—SPECIAL CENTRIFUGE TUBE CARRYING SODIUM CITRATE SOLUTION FOR COLLECTION OF BLOOD FOR SECURING SERUM FOR INTRASPINAL INJECTION.

3. A few minutes after injection 25 c.c. of blood is removed with a syringe from the same or opposite arm and placed in a large sterile centrifuge tube carrying 1 c.c. of a sterile 10-per cent. solution of sodium citrate in water (Fig. 81) and gently mixed.

Centrifuge tube on the left carrying 1 c.c. of a sterile 10 per cent. solution of sodium citrate in water; the tube on the right after 25 c.c. of blood has been added.

4. The citrated blood is centrifuged at once and the plasma transferred to a second sterile tube and centrifuged again unless absolutely clear.

5. The cubic centimeter of solution of neoarsphenamin is now diluted with 49 c.c. of sterile saline solution and 1 c.c. added to the plasma. This represents a dose of 0.001 gm. (1 mg.) of neoarsphenamin which is seldom exceeded, although 0.002 gm. has been repeatedly injected without untoward effects.

6. The neoarsphenamized plasma is now heated in a water-bath at 56°C. for thirty minutes.

7. Spinal puncture is done immediately with the patient on his side and about 5 c.c. of spinal fluid collected for routine examinations. With a gravity apparatus about 15 c.c. of spinal fluid is allowed to collect in the receptacle, the neoarsphenamized plasma is poured in and the mixture slowly injected.

8. The puncture site is cleansed, sealed with collodion and the patient is kept in bed for eighteen to twenty-four hours or at least over night.

With this method both intravenous and intraspinal injections are given in two hours or less. It is to be noted that the method as now practiced has been modified from the original by the use of neoarsphenamin, the use of a smaller amount of sodium citrate, the omission of spinal drainage and the thorough dilution of the neoarsphenamized serum with spinal fluid before injection.

Intraventricular and Intracisternal Methods of Administration.—The treatment of neurosyphilis by injection of arsphenamized and neoarsphenamized serum into the lateral ventricles and cisterna magna is still in the experimental stage. Cistern puncture is not much more difficult than spinal puncture, but injections should be made very slowly; in my limited experience I have not observed any better results than those which have followed lumbar injections and I believe the latter are safer. When intracisternal treatments are given, I believe the Swift-Ellis method as described in this chapter is the method of choice because least likely to produce local irritation. If the compounds themselves dissolved in saline solution or serum are injected, I believe that preference should be given sulpharsphenamin and neoarsphenamin because these are less irritating than arsphenamin. The technic of cistern puncture is described on page 857.

Intraventricular injections have been given with success, but the first injection requires a general anesthetic and a small trephine, as described on page 858. I have had no experience with the method but when practiced would advise the Swift-Ellis method as described above for lumbar injections as being least likely to produce irritation although neoarsphenamin has been introduced as in Marinesco's intraspinal treatment without apparent injury.

Method for the Oral Administration of Arsphenamin.—I have already discussed the results of animal experiments and clinical experience by Schamberg and myself[9] with the oral administration of arsphenamin and the indications for this route of administration in selected cases; the formula employed by us for each capsule was as follows:

Arsphenamin	0.03 gm. (gr. ½)
Sodii hydrosulphit	0.015 gm. (gr. ¼)
Bismuthi subgall	0.12 gm. (gr. 2)

A capsule is given after each meal. The sodium hydrosulphite is added to prevent oxidation of the arsphenamin and bismuth is included to correct any tendency to looseness of the bowels. Three capsules a day administers 0.09 gm. arsphenamin and some patients have taken the capsules continuously for a period of six weeks without complaint. Owing to the expense, however, only selected cases can be given arsphenamin by this route although there is no doubt that some therapeutic effects are exerted.

Methods for the Rectal Administration of Arsphenamin, Neoarsphenamin and Sulpharsphenamin.—Within recent years a series of reports have appeared in the literature bearing upon the rectal administration of arsphenamin and neoarsphenamin in the treatment of selected cases of syphilis and especially in nervous or obese women and infants to whom intravenous or intramuscular injections cannot be given. I have already reviewed these reports, but here it may be stated that this route of administration is occasionally useful under certain circumstances as in the case of syphilitics who must travel, individuals who are very obese or with other conditions rendering intravenous injections impracticable; the methods of administration are as follows:

First Method.—Suppositories containing 0.1 gm. of arsphenamin, 0.2 gm. of neoarsphenamin or 0.2 gm. of sulpharsphenamin may be given every other day for six weeks at a

time. Neoarsphenamin and sulpharsphenamin are less irritating than arsphenamin. The inclusion of a very small dose of extract of opium is sometimes required. The suppositories should be inserted after the bowels have been emptied or at least twelve hours before the next evacuation, so that complete absorption may occur. It is my practice to administer them at bed time because the prone position aids in retention.

This method has been particularly advocated for the treatment of congenital syphilis but as recently stated by Littmann and Hutton,[9A] the clinical results obtained by the use of arsphenamin by rectum in children with acute manifestations of syphilis are too feeble to warrant consideration and especially since intramuscular injections of sulpharsphenamin or even of neoarsphenamin are more satisfactory if it is impossible to give these compounds intravenously.

Second Method.—Solutions of arsphenamin, sulpharsphenamin or neoarsphenamin may be injected once or twice a week; neoarsphenamin and sulpharsphenamin are preferred because less irritating. The dose of neoarsphenamin for adults is 1.8 gm., although as much as 4 gm. has been given at one time without irritation; the dose of sulpharsphenamin for adults may be 1.2 gm. The bowels should be evacuated and an enema given one or two hours before the injection. If the bowels are regular, I do not prescribe a cathartic and believe it better not to do so because the injection is sometimes expelled before absorption by subsequent evacuations. But even though the bowels have been evacuated it is well to give the enema an hour or two before the injection of drug. Two ampules of 0.9 gm. each of neoarsphenamin or two ampules of 0.6 gm. each of sulpharsphenamin are dissolved in about 30 c.c. (two ounces) of water. A greased enema tube with a small funnel attached is introduced into the rectum and the solution allowed to flow in gradually as in the administration of an enema, followed by an ounce or two of warm water to wash in all of the drug. Care must be taken against expulsion of the fluid and it is generally necessary for the patient to remain lying down for at least an hour. Patients may be taught to dissolve the drug and to administer it to themselves in their own homes; ordinary tap water may be employed since sterile precautions are not required. As a general rule, the injections should be given at bed time when self-administered by the patient as absorption is practically completed by morning.

Third Method.—Arsphenamin, neoarsphenamin or sulpharsphenamin may be rubbed up into a suspension in one ounce of cotton seed oil and injected into the rectum by the physician followed by an additional ounce of oil to wash in all of the drug. This method is to be preferred when arsphenamin (dose 0.6 to 1.2 gm.) is being administered, as the oil reduces the degree of irritation; with neoarsphenamin and sulpharsphenamin, however, water solutions as described above are usually well borne although if irritation results suspensions in oil are less irritating.

As a general rule, quite a series of injections can be given by any of these methods before the bowel becomes intolerant.

Methods for the Local Application of Arsphenamin and Neoarsphenamin. *For the Treatment of Syphilitic and Frambesial Ulcers.*—As discussed in Chapter XXIII, the local application of arsphenamin and neoarsphenamin in sufficient strength results in the destruction of those spirochetes with which the drugs come in contact. Owing to the expense of the compounds, however, they have not been employed as dusting powders for chancres and other open infectious syphilitic lesions; but I have employed with success dusting powders of one part arsphenamin or neoarsphenamin with two parts of zinc oxid. A powder of one part arsphenamin or neoarsphenamin with two parts of calomel is particularly efficacious for the local treatment of chancres after the secretions have been removed with cotton and warm water. Neither drug produces local irritation when so applied once or twice daily. Alston[10] has reported beneficial results in the treatment of the ulcers of frambesia tropica by local applications of 1:3 powders of arsphenamin or neoarsphenamin. Of course in both syphilis and frambesia, local applications are only of slight value of brief periods of time, since the lesions are usually quickly healed by intravenous injections. But in the treatment of chronic ulcers resistant to treatment local applications are sometimes indicated.

For the Treatment of Spirochetic Gingivitis.—As discussed with more detail on page 362, not a few cases of gingivitis (pyorrhæa alveolaris) show enormous numbers of spirochetes in smears of the secretions. Of course, these are not *Spirochæta pallida*, unless syphilitic mucous patches are present,

but rather an increase of one or more varieties of other species of spirochetes present in the mouth. Apparently these spirochetes are not harmless in cases of this sort and are capable of eliciting severe inflammatory reactions as seen in cases of "trench mouth." Sometimes fusiform bacilli are present indicating a Vincent's infection of the gums.

In all of such cases showing the presence of enormous numbers of spirochetes, the local application of arsphenamin or neoarsphenamin is of distinct value when thoroughly applied at frequent intervals along with the removal of tartar deposits and other surgical procedures.

An excellent method of administration is the local application of 2-per cent. solutions of arsphenamin or 4-per cent. solutions of neoarsphenamin; these are best applied by a dental surgeon who may inject a drop or two of solution deep into each of the pockets by means of a 2 c.c. syringe fitted with a small blunt, curved needle (Fig. 82). The solution should be squirted

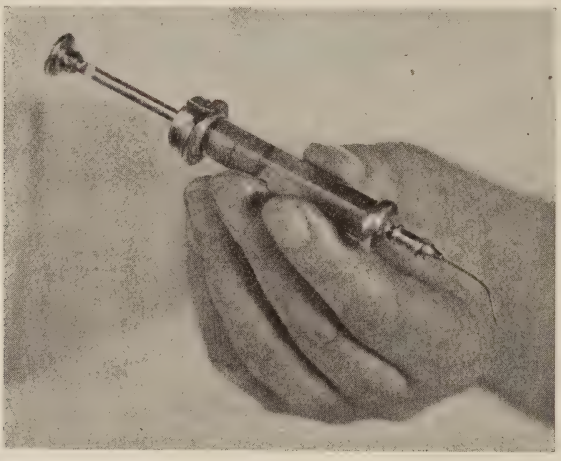

FIG. 82.—SYRINGE AND NEEDLE FOR APPLICATION OF SOLUTIONS OF ARSPHENAMIN IN THE TREATMENT OF GINGIVITIS.

between the teeth and into the pockets in a painstaking manner, due care being observed, however, against injuring the gums with the needle in order to guard against carrying the infection into healthy tissues.

The frequency of applications depends upon the severity of the infection; in acute severe infections daily or twice daily applications are required until improvement results.

The solutions may be prepared as follows:

1. Dissolve 0.6 gm. arsphenamin in 30 c.c. of a hot sterile 50 per cent. solution of glucose. This gives a 2-per cent. solution. It is not necessary to alkalinize the solution as the acid solution is more spirocheticidal and does not oxidize as rapidly. The glucose also aids in preventing oxidation. The solution is now distributed in 1 c.c. glass ampules which may be sealed *in vacuo* by carefully heating the neck until the air is expelled by expansion followed by sealing. Ampules prepared in this manner keep almost indefinitely and even should slight brownish discoloration occur as a result of oxidation, the spirocheticidal properties are not reduced, although solutions which have turned a deep brownish-green-black color should not be employed because so much reduction of the arsphenamin has occurred, that curative properties may be reduced.

2. If neoarsphenamin is employed a 4-per cent. solution may be prepared by dissolving the usual ampule of 0.9 gm. in 22.5 c.c. of cold sterile 50-per cent. solution of glucose in water. The glucose greatly retards oxidation and is preferable to plain water or saline solution. This solution is now distributed in 1 c.c. ampules and sealed *in vacuo* in the same manner.

The local application of these solutions produces no irritation; ordinarily 1 c.c. of either is sufficient for a treatment when carefully applied. The taste may be removed by spraying the mouth with cinnamon water or some similar preparation.

If smears show that many bacteria are likewise present, and most cases of chronic gingivitis are mixed spirochetic and bacterial infections, it is advisable to apply a bactericide at the same time. For this purpose I can highly recommend a solution of mercurophen in conjunction with neoarsphenamin or arsphenamin. All that is necessary is to have on hand a stock solution of 1:500 mercurophen in water which keeps indefinitely; 1 c.c. of 4-per cent. solution of neoarsphenamin or 2-per cent. arsphenamin is drawn into a syringe followed by 1 c.c. of the mercurophen solution. The compounds mix well and may be applied together at the same time. If mercurophen is not available, metaphen or the succinimid of mercury may be employed in similar strength, but other soluble mercurials are precipitated and cannot be used in the same syringe. Not infrequently cases relapse after treatment has been suspended and during the past several years I have been experimenting with dental creams into which arsphenamin has been introduced for prophylactic use by infected individuals. Any good dental cream may be employed, the following formula having proved quite agreeable and efficacious:

Arsphenamin	1.0 gm.
Mercurophen	0.2 gm.
Dental cream	100.0 gm.

This cream contains therefore 1:100 arsphenamin and 1:500 mercurophen; to it may be added 1 gm. of sodium hydrosulphite to reduce oxidation, but the sulphur odor and taste are disagreeable to some individuals and the mixture as given keeps very well in collapsible tubes.

It is poisonous on account of the mercurophen, but not dangerous even though minute amounts are swallowed, although the patient should be warned against swallowing the paste. The mercurophen, however, may be omitted when bactericidal action is not required. Experiments have shown that this cream is highly spirocheticidal and bactericidal when brought in contact with gingival secretions and sputum; it has likewise proven prophylactic for syphilis of rabbits when applied immediately or almost immediately after scrotal inoculations. If the secretions are very acid, the dental cream should be alkaline or made alkaline by the addition of sodium bicarbonate.

I generally advise patients to apply a small amount of the paste with their fingers to the infected portions of the gums, rubbing it in well between the teeth and into the pockets. After a minute or two the teeth and gums are carefully brushed with warm water in the usual manner.

I believe that the routine or frequent use of a preparation of this kind aids in maintaining the gums in a healthy state after the gingivitis has been cured totally or in large degree; it also is useful in the treatment of gingivitis.

For the Treatment of Vincent's Angina.—I have discussed on page 361 with more detail the treatment of Vincent's angina with arsphenamin and its substitutes, but here it may be stated that local applications of these compounds are frequently useful; intravenous injections, however, are sometimes required in very severe cases.

Either arsphenamin or neoarsphenamin powders may be applied directly to the exudates and involved tissues, although solutions are probably better applied and more efficacious. Either 2-per cent. solutions of arsphenamin or 4-per cent. solutions of neoarsphenamin in 50-per cent. glucose solutions may

be employed as described above for the treatment of spirochetic gingivitis. The following solution in glycerin, however, has appeared in my experience to be somewhat better:

Dissolve 0.6 gm. arsphenamin in 15 c.c. of hot 50-per cent. glucose in water; when completely dissolved add 15 c.c. of glycerin and mix. This gives a 2-per cent. solution of arsphenamin in 50-per cent. glycerin and the mixture may be dispensed in an ordinary bottle as it oxidizes but very slowly and may be used until the solution becomes a very dark brown or black color, at which time it should be discarded. If neoarsphenamin is employed, 0.6 gm. should be completely dissolved in 7.5 c.c. of 50-per cent. glucose in water and 7.5 c.c. of glycerin added; this gives a 4-per cent. solution in 50-per cent. glycerin which may be dispensed in the same manner. Plain water may be used instead of glucose solution for either compound, but glucose greatly aids in retarding oxidation.

Either solution should be thoroughly applied with cotton swabs every three hours until the infection is brought under control; the intervals of application may be then lengthened. The disagreeable metallic taste may be removed by rinsing the mouth with diluted *liquor antisepticus* or some similar preparation.

CHAPTER LXIII

TECHNIC OF VARIOUS METHODS FOR THE ADMINISTRATION OF MERCURY IN THE TREATMENT OF SYPHILIS

Since the toxic and therapeutic effects of mercury vary with the compound selected and route of administration, it is not surprising that a large number of different compounds and mixtures have been advocated for the treatment of syphilis.

Choice of Compounds and Methods of Administration.—With regard to the choice of compounds and methods of administration I can do no better than to quote Fournier: "There is no remedy which suits every case. The choice of mercurial medication should not be based on theoretical considerations, but on clinical indications relative to the peculiarities of the patient and the quality of the disease, which are essentially variable and often impossible to foresee. The best method is that which is tolerated by the patient, and which has an active influence on the symptoms, and this can only be found by experience. Absolutism is out of the question, and the physician

who has the interests of his patient at heart will approach treatment without prejudice and without any preconceived plan, and quite prepared to sacrifice his favorite method for some other which may be more adapted to the indications of the particular case." Again, "if the patient is dyspeptic, or subject to diarrhea, the method of ingestion is contra-indicated, as it may increase the gastro-intestinal intolerance. In certain cases it may be necessary to prescribe several therapeutic agents simultaneously, and under these conditions mercury should be administered externally, leaving the stomach free for other remedies. There are also indications with regard to age. In young children the digestive functions must be respected, which are so vulnerable at this age, and mercurial inunction is better than ingestion at this period of life. Lastly, there are certain private considerations which may contra-indicate certain methods. For instance, if a married man wishes to be treated without the knowledge of his wife, mercurial inunctions will hardly be suitable.

"Therefore, owing to numerous and diverse reasons, the choice of a method of mercurial administration cannot be determined in a general or abstract manner. The choice is subject to the necessities of practice, to special circumstances, and to individual considerations. In fact, everything is subordinate to the indications of the particular case and these indications must always be obeyed."

Method of Ingestion.—The method of ingestion, which is called sometimes the buccal method or the stomachic method, has been unquestionably the favorite method for the administration of mercury; Fournier spoke of it as the "true method of the treatment of syphilis" and Hutchinson likewise had little or no use for other methods.

Advantages and Disadvantages.—This method possesses the distinct advantage of convenience; it is well adapted for the prolonged administration of mercury, that is, with intermittent periods of rest. When prescribed in the form of pills or tablets, the ease of administration removes all fear of detection. As a general rule, there is much less danger of salivation and stomatitis; at least, the administration may be stopped upon the first signs of these with a rapid disappearance of untoward effects. There is likewise less danger of renal irritation and nephritis than in other methods of administration.

On the other hand, gastro-intestinal disturbances are more likely to occur by this route, although it is possible to avoid or correct them in the great majority of cases by a proper choice of compound and regulation of dosage. For this reason the method of ingestion is not well adapted for those patients presenting evidences of gastro-intestinal or hepatic and gall-tract disturbances. Furthermore, for rapid effects the method is inferior to inunction and injection so that we rarely depend upon mercury by any method of administration at the present time in the treatment of acute syphilis, giving preference to arsphenamin or one of its substitutes or even bismuth, and least of all to mercury by ingestion; if mercury must be given under these circumstances, preference is to be given injections or inunctions. Clinical experience and the results of the Wassermann reaction have shown that the therapeutic effects of mercury administered by ingestion are not good or acceptable insofar as the ultimate and complete cure of syphilis is concerned. It is true that the manifest lesions may be dissipated, but the incidence of tertiary lesions, and especially of the central nervous system, are known to be higher than develop in cases of syphilis treated more intensively with mercury or with arsphenamin or one of its substitutes. Mercury by ingestion may be quite worth while along with more intensive treatment with arsenic

or bismuth and at the tail end of prolonged treatment resulting in clinical and serological "cure," as a matter of additional safeguard and security, but the opinion of most syphilologists to-day is that mercury by mouth should not be relied upon for the cure of syphilis to the exclusion of more active forms of mercurial therapy or the administration of more active spirocheticidal agents.

Contra-indications.—The method of ingestion, therefore, is not without certain contra-indications which have been summarized by Fournier as follows:

1. When the patient is affected with some gastro-intestinal disorder or is peculiarly hypersensitive to mercury by this route of administration.
2. When it is imperative not to disturb the digestion of a patient who is in need of nutritional improvement.
3. When it is necessary to leave the gastro-intestinal tract free for other remedies which may be required.
4. When there is pressing and urgent need for rapid or almost immediate mercurialization.

Plan of Administration.—In all cases the administration of mercury should be intermittent, that is, for three to six weeks followed by two to four weeks of rest.

One may give a fixed dose over this period of time, provided it is well tolerated, or one may give ascending doses to determine the individual tolerance followed by the subsequent administration of the maximum tolerated dose for the chosen period of medication. For example, if the protiodid is prescribed in ¼ grain tablets, one may give three a day after meals for two or three days, followed by four a day, five a day, six a day, etc., until signs of enteritis or salivation appear, at which treatment is interrupted for a few days until these symptoms disappear, to be resumed with the maximum dose free of all effects.

Preparations, Doses and Methods of Administration.—A great number of compounds of mercury have been advocated for ingestion, among which the bichlorid, protiodid, mercury with chalk, blue mass and calomel have received most attention. For all practical purposes the first three are sufficient.

The *bichlorid* is said to be less likely to produce salivation and stomatitis; Fournier thought it was especially useful for treatment in the late or chronic stages of syphilis, while the protiodid was to be preferred for the early stages. Bichlorid is more likely than the other preparations to produce gastric disturbances of pain, cramp, and strange sensations—sublimate gastralgia—although intestinal disturbances of cramp and diarrhea are less common than with the protiodid. Women are less tolerant than men—so much so that Fournier thought that sublimate was not a remedy for women. The average dose for men is ½ grain per day (0.03 gm.); for women, about ⅓ grain (0.02 gm.) per day.

The bichlorid may be administered in various ways; one of the oldest formulas for liquid administration is *Van Swieten's liquor:*

℞ Hydrarg. bichlor. corros. ..... 1 gm.
Alcohol ..... 100 c.c.
Aq. distillat ..... 900 c.c.

This is, therefore, a 1:1000 solution, so that a tablespoonful carries about 0.015 gm. or ¼ grain of the compound. The dose is usually a tablespoonful after breakfast and after the evening meal, constituting ½ grain (0.03 gm.) daily. The taste, however, is disagreeable and especially to women, although this may be disguised somewhat by taking the mixture in a wineglassful of milk.

An old favorite is the 1, 2, 3 mixture as follows:

℞ Hydrarg. bichlor. corrosiv. ..... gr. 1 (0.06 gm.)
Potassium iodidi ..... ʒ II (7.2 gm.)
Syr. sarsaparil ..... f℥ III (100 c.c.)

Two teaspoonfuls are given after each meal (¼ grain daily) and possibly again at bedtime (⅓ grain daily).

As a general rule, however, pills are much more convenient and preferable to most patients. A good formula is that of Fournier, a modification of the old Dupuytren pill:

℞ Hydrarg. bichlor. corrosiv.
Ext. opii.....āā 0.3 gm. (5 gr.)
m. Div. Pil. No. XXX

Each pill contains ⅙th grain (0.01 gm.); the dose for men may be a pill after each meal (½ grain or 0.03 gm. daily) and for women a pill after breakfast and the evening meal (⅓ grain or 0.02 gm. daily).

The *protiodid of mercury* (*hydrargyrum iodum flavum* or *viride*) is more likely than bichlorid to produce salivation, but is better tolerated by the gastro-intestinal tract. Sometimes, however, it produces an initial diarrhea, the "diarrhea of apprenticeship" of Fournier, but this is readily checked by temporarily stopping the administration for a few days. Protiodid of mercury is given in pills or tablets, since the compound is insoluble, and is probably the favorite at present for the ingestion treatment of syphilis.

The drug is somewhat better borne than bichlorid and the dose for men may be 1 to 2 grains per day (0.06–0.12 gm.); women require a little less, 1 to 1½ grains per day (0.06–0.09 gm.). Tablets are usually procurable containing ¼ grain (0.02 gm.) each, and 4 to 6 may be given daily in divided doses after meals. It is sometimes advantageous to incorporate opium and especially if there is a tendency to colic and diarrhea; for this purpose Fournier's modification of the old Record pill is to be recommended:

℞ Hydrarg. iod. flav..... gr. xxx (1.5 gm.)
Ext. opii..... gr. V (0.3 gm.)
m. Div. Pil. xxx

Each pill contains about 1 grain (0.05 gm.) of protiodid and ⅙th grain (0.01 gm.) of extract of opium; the dose is 1 or 2 pills a day after meals.

If pills are procured already prepared, it is well to inspect them, because if old and stale they may be very hard and likely to pass through the intestinal canal without absorption.

Mercury with chalk (*hydrargyrum cum creta*) was the old favorite of Sir Jonathan Hutchinson; I have found that it is sometimes better borne than either sublimate or protiodid. Tablets are usually procurable, containing 1 grain in each; Hutchinson usually included 1 grain of Dover's powder as follows:

℞ Hydrarg. cum cret.,
Pulv. ipecac. et opii.....āā grs. xxx (2.0 gm.)
m. Div. Tabl. No. xxx

One pill or tablet is taken after meals; if the mercury is unusually irritating, the dose of Dover's powder may be increased.

If pills are purchased already prepared it is advisable to inspect them, as they may be so hard as to pass through the intestinal canal without absorption; tablets or capsules are to be preferred.

Blue mass (*massa hydrargyri*) and calomel (*hydrargyri chloridum mite*) are not widely employed at the present time for the treatment of syphilis, although either may be administered in dose of ⅙ to ¼ grain three or four times daily. Saxl [1] has recently advocated as 1-per cent. suspension of calomel in dose of twenty drops (approximately ⅙th grain), increased to forty, three times a day after meals. He states that in this dose it is well borne for months at a time and that stomatitis is rare. In my experience, however, colic and diarrhea frequently develop and I believe calomel is quite inferior to the protiodid and mercury with chalk.

Method of Inunction.—This is the oldest method of all for the administration of mercury in the treatment of syphilis and I believe one of the most efficient *when properly applied.* It has been both greatly praised and condemned and undoubtedly possesses distinct disadvantages, but likewise distinct advantages. Many deplorable accidents and fatalities have been ascribed to the method in the old days when patients were subjected to unnecessarily severe treatment with baths, steamings, excessive doses and salivations, but there is no excuse for such gross errors to-day, although it is true that best results are secured when the method is practiced with appropriate bathing and possibly aided by the drinking of sulphur waters.

Advantages and Disadvantages.—The chief advantage of mercurial inunctions are the prompt therapeutic effects, when the method is properly applied and especially by skilled rubbers; the method is particularly desirable for the treatment of severe cases, such as cerebral or spinal syphilis, visceral lesions, and syphilis of the eye threatening vision, when arsphenamin and its substitutes cannot be given. It is a safe method when properly supervised and gastro-intestinal disorders are infrequent. It is painless. It leaves the stomach free for other remedies or for improving nutrition by extra dietary regulations, which is frequently very important in the treatment of syphilis of infants and children.

On the other hand, it is dirty, when the usual mercurial ointment is employed, apt to be repugnant to patients and sometimes compromising from the staining of underclothes, night clothes, bed linens, etc. Furthermore, many patients will not apply it correctly, persistently or consistently, even though they may claim to do so. In other words, it is a difficult method to have done correctly unless minute directions are given or a professional rubber is employed.

It is more likely than other methods to produce salivation and stomatitis, the latter frequently being unusually severe, generalized and of sudden onset, although these ill effects are readily avoidable by due preliminary preparation of the teeth and gums, by daily cleansing of the mouth and by proper regulation of dosage. Inunctions sometimes produce lassitude, vague muscle pains in the back and legs and loss of weight, but such patients are not likely to bear well with mercury in any form of administration.

Inunctions also tend to irritate the skin and may produce various local and generalized forms of dermatitis; the method cannot be applied to those with tender skins, when there is much scarring as after small-pox, or when the skin is thickened, as in ichthyosis.

Preparation, Dosage and Methods of Administration.—As a general rule, the U.S.P. *unguentum hydrargyri* is employed; this is 50-per cent. mercury in suet and lard. The usual adult dose is one dram once a day, but in grave and rebellious cases of syphilis the dose may be increased to two or three drams per day. Infants may receive as much as 15 to 30 grains per day, since they are less likely to develop stomatitis.

The preparation used at Aachen (²) and highly recommended is a 33⅓-per cent. ointment as follows:

℞	Hydrarg. pur	100 gm.
	Adeps lanae	15 gm.
	Ol. olivae	3 c.c.
	Adeps	112 gm.
	Sevum ovis	70 gm.
	Phenolis	3 gm.
	M Div. 60	

This gives 60 doses in waxed papers of 5 gm. each. After a patient has been using these for a time and becomes accustomed to the size of the dose, the ointment may be prescribed in a jar (being cheaper) and the patient trusted to use approximately the correct amount removed with a spoon or the fingers. The phenol may be omitted if objectionable. The adult dose is 5 grams for a twenty minute rub, 7 grams for a thirty minute and 10 grams for a forty minute rub.

At the Hot Springs in this country the blue ointment (50 per cent.) is employed, an ounce being divided into four, six or eight equal parts, one part being used for each inunction. The patient usually takes a hot bath some time after breakfast and then repairs to the "rubbing parlor," where the inunction is applied to the back by a professional rubber for twenty to twenty-five minutes, the patient sitting astride a chair. He then puts on a thin undershirt, which is used as a "mercury shirt" for one week without change, the inunction usually being given daily until signs of salivation are noted.

At Aachen the patient begins in the morning by drinking from one to three glasses of the sulphur water, followed by a bath in a room heated to 70°F. and in water from 95° to

100°F., for ten to twenty minutes, the time varying according to the robustness of general health, being brief for the enfeebled and elderly tabetics. This is followed by rest and breakfast in bed, to be followed soon after by application at the hands of an expert rubber of 5 to 10 grams of the 33⅓-per cent. ointment, the amount varying according to circumstances. As a general rule, the thighs, calves, arms and back are treated in turn from day to day; the hands should never be unpleasantly cold, and it is advisable that all hair be removed from the parts to be rubbed. Unquestionably one of the principal objections to inunctions is the dirty gray color of these preparations and consequently discoloration of the skin and garments. As stated in preceeding chapters, I have found in collaboration with Schamberg, Raiziss and Gavron[3] that inunctions of calomel are apparently absorbed and in practice I have seen salivation and good therapeutic results. I believe, therefore, that calomel ointment may be substituted for blue ointment, although Cole and Littman[4] claim that it is inferior. Since calomel contains 85 per cent. of mercury, the ointment must be stronger in proportion than blue ointment; I have used the following formula for several years:

℞ Hydrarg. chlor. mit..... 130 gm. (℥iv)
Lan.
Adeps benz.....āā 35 gm. (℥ix)
M. Div. 50

The dose is the same as for 50 per cent. blue ointment, being one dram (4 gm.) per day.

Recently Cole, Hutton and Sollmann[5] have advocated a clean method of inunction with the usual blue mercury ointment which consists in rubbing for thirty minutes followed by washing off the skin with benzine and cotton. By this method they found that mercurial inunctions were fully as efficient as when the ointment was kept on the skin. By either this or the old method, about half of their patients required from eleven to nineteen rubs before salivation occurred; about a fourth required a smaller and a fourth a larger number. Unquestionably this is a good method when the matter of objection from the standpoint of the discoloration of the skin, etc., becomes of importance, but, as stated in Chapter LIII, my experiments with rabbits have shown that there is not as much absorption after rubbings with either blue or calomel ointment when the skin is washed with benzine as when the excess is allowed to remain as in the usual method.

In private practice when the inunctions are given by the patient himself or by a member of the family, they are generally most convenient at bed-time and the following routine may be employed:

1. For success the patient must be impressed with the necessity of carrying out the method consistently and persistently. Of the elderly or partially crippled (as in advanced tabes), it is almost useless to depend upon the patient for applying the inunctions; in such circumstances the services of a nurse, professional rubber or a member of the family must be secured. Physicians will do well to keep ever in mind that many patients, even those who are young, robust and with plenty of time to apply the treatment, show a tendency to disregard directions after a few applications unless they are duly impressed with the seriousness of the disease and the danger to future health and well-being of negligence on their part.

2. A hot bath is taken for five to ten minutes, followed by thorough drying.

3. The rubbings are applied to different parts of the body in rotation, to avoid irritation of the skin:

1st day:	left side of thorax.
2nd day:	right side of thorax.
3rd day:	inner surface of the left thigh.
4th day:	inner surface of right thigh.
5th day:	inner surface of left arm.
6th day:	inner surface of right arm.

If applied by a professional rubber or some member of the family, the back may be chosen for the seventh day. The hand may be protected with a rubber glove and nurses and rubbers should be particularly careful to keep their hands and mouths in good condition and to take plenty of out-door exercise.

4. The hand should be warm and the ointment not too stiff or too soft. Hairy portions of the body should be avoided. In male patients it is sometimes advisable to shave the thighs. Inunctions of the thighs and calves of the legs are especially good for tabetics, because of the mental impressions given and the massage of the muscles.

5. The dose is ordinarily one dram of the U.S.P. 50-per cent. mercury ointment, five drams of the 33⅓-per cent. Aachen mercury ointment or one dram of the 85-per cent. calomel ointment. The time of rubbing should be at least 10 to 20 minutes for these doses; larger doses of all three may be used in some cases up to double these amounts, the time of rubbing being increased accordingly up to forty minutes.

6. If mercury ointment is employed, the skin may now be washed off with benzine and cotton and the usual night clothes donned; when this method is practiced, it is well to rub for thirty minutes instead of twenty minutes. I believe, however, that it is better to leave the excess on the skin and to don a thin shirt if the application has been to the thorax or arms, or thin underdrawers or pajamas if the application has been to the legs. The same garment should be worn for at least one week and it is helpful to use lavender colored pajamas to disguise discoloration from mercury ointments. With calomel ointment there is no difficulty at all.

7. Next morning the skin may be bathed as usual and all traces of the ointment removed; it is well to dust the anointed area with talcum powder.

8. The duration of treatment is ordinarily about three or four weeks followed by a rest of two weeks and inunctions again for three weeks until sixty to ninety rubs have been taken, provided they are well borne. It is prudent to discontinue as soon as the gums are affected or the patient debilitated.

9. Inunctions may be taken instead in the morning after a bath, the excess being left on and the same suit of underwear worn for a week, or the excess of mercury may be removed with benzine. It is well, however, to rub for thirty minutes if the latter method is employed.

10. Artificial sulphur water may be taken daily at the same time.

In addition to this method of inunction, *methods of mercurial plasters*, *baths with mercurial soap*, etc., have been advocated and practiced but not usually within recent generations and they are now largely only of historical interest.

Methods of Inhalation and Fumigation.—In the fifteenth century a favorite method of administering mercury was to place the patient in a tent with a brazier to vaporize the drug along with aromatic resins and other substances and allow the half-suffocated victim to inhale the vaporized mercury (method of inhalation) and to have it deposited on the skin (method of fumigation). As practiced at that time along with barbarous preparatory and follow up measures, the method resulted in many fatalities, due principally to absorption of excessive amounts of mercury with poisoning and especially salivation and stomatitis. These methods have, however, come down to the present time but with progressive improvements in technic, so that they are much less dangerous and have some adherents, especially in Europe.

For the inhalation method special apparatus is employed for vaporizing the mercury, calomel or the metal being commonly employed, and breathing it deeply into the lungs. Mercury is deposited in the fauces and a portion is swallowed. I have already discussed in Chapter LII the pros and cons of absorption by this method.

Recently Engelbreth[6] has reported upon the treatment of 1300 cases of syphilis of all stages with more than 60,000 inhalations without one misadventure. A water-bath apparatus was used for volatization in hospital practice and an electric volatizer for home use. In a matter of ten minutes it is claimed that a dose of 0.090 gm. (1⅓ grains) of mercury is inhaled. Various other apparatus have been described from time to time, but I have had no practical experience with any of them and am not in position to express any opinion on their merits or demerits. Doubtless inhalation methods can be made safe and to some extent agreeable, but I surmise great care must be taken of the mouth and throat and against excessive doses since all the accidents of over-dosage ascribed to mercury in general have occurred from inhalations of mercury.

Method of Intramuscular and Epifascial Injection.—Injections of mercury were first practiced by the subcutaneous route, but this method has been almost entirely abandoned in favor of the intramuscular and epifascial routes for both soluble and insoluble salts.

Advantages and Disadvantages.—The epifascial and intramuscular injection of mercury are probably the most popular routes of administration today when prompt and definite mercurialization is required. They insure more

exact dosage than the methods of ingestion and inunction, although when the insoluble salts are injected, absorption is by no means regular or uniform. When the soluble salts are injected, however, absorption is fairly rapid and regular. Injections, therefore, remove the possibility of deceit and deception on the part of patients who may readily enough avoid inunctions or ingestion.

Injections also spare the gastro-intestinal tract and leave it in good condition for purposes of nutrition or the administration of other remedies, although gastro-intestinal disturbances of colic and diarrhea, as well as salivation and stomatitis, may occur when the tolerance of the patient is exceeded.

The chief advantage, however, is the promptness of mercurialization and therapeutic effects and especially when the soluble salts are administered. From these standpoints there can be no denial of the fact that injections are superior to ingestion and inunction.

When the insoluble salts are administered, the injections are given but once a week or ten days and many patients find this practice more convenient and less annoying than other methods of administration.

The disadvantages, however, are the pain, swelling and nodosities with accompanying discomfort and interference with sitting, walking, etc., which may follow intramuscular injections even when administered in a very careful and skilfull manner; this is especially true of those who are lean and spare.

When the soluble salts are administered, an injection is required every day for a month as a course or three times a week for two months, and this may be very irksome to the patient and tends to advertise his malady. Such methods are applicable in hospitals and sanatoriums, but much less so in private practice and especially in small communities where, as Fournier intimates, an individual's business is everyone's business and where a daily visit to the office of a physician is almost sure to be a subject of comment and gossip.

Soluble versus Insoluble Compounds.—The soluble salts are absorbed more promptly and uniformly; therefore, explosive toxic effects, as sudden salivation, stomatitis or nephritis are much less likely to develop than when the insoluble salts are injected. The soluble salts in water or saline, however, are apt to produce more pain and tenderness, although these may be greatly reduced by administering them dissolved or suspended in a vegetable oil like almond oil or palmitin. Their chief advantages, therefore, are rapidity and intensity of therapeutic effects with better control on the prevention of ill effects; their chief disadvantages are the frequency (daily or thrice weekly) with which they must be given.

The insoluble salts mostly employed at present are the salicylate, calomel and gray oil. Calomel undoubtedly gives the best therapeutic results, but likewise the most pain and nodosities; the salicylate is by all odds the most popular at present of the insoluble preparations.

Their chief advantage is the infrequency of injections, being administered not more frequently than once a week or once every ten days unless smaller doses are given biweekly. The old method of giving 3 to 6 grains of calomel at one time at long intervals has been abandoned, because of the fearful explosive reactions of stomatitis, gastro-enteritis and even fatalities that attended this practice. For most patients an injection once a week of the salicylate in dose of 1 grain is a very agreeable and convenient method of taking mercury.

The chief disadvantage aside from the pain and resulting disability is irregular absorption. As shown by Schamberg, Raiziss and myself[7] the mercury contained in them is just as poisonous as in the soluble salts, but it is yielded up to the circulating fluids at a very slow rate. We have shown that in the muscles of rabbits about 50 per cent. of the mercury of calomel, the salicylate and gray oil remains inabsorbed in the body, even as late as 6 or 7 weeks after injection. The daily rate of absorption in these animals was calculated at about one to one and a half per cent. a day, and weekly injections therefore may be progressively cumulative. Doubtless however, absorption is more rapid in human beings as the result of more exercise and muscular movements.

Methods of Administration.—As stated above subcutaneous injections are no longer practiced. The injections may be given intramuscularly or epifas-

cially (intermuscularly) as described in Chapter LX, preference being given the muscles of the buttocks.

Preparations, Doses and Methods of Administration of the Soluble Salts.—Of the soluble salts the bichlorid, succinimid, benzoate, cyanid and mercurosal are most employed although a host are to be found mentioned and advocated in the literature.

Of these the *succinimid* is probably one of the best; the dose is ⅙ to ¼ grain (0.01 to 0.015 gm.) daily, the following formula having been used by me for several years with uniform success:

℞	Hydrarg. succinimid	2.6 gm. (gr. xl)
	Butyn	0.5 gm. (gr. vii)
	Aq. sterilat	100.0 c.c. (f ℥iiiss)

Of this solution 1 c.c. (16 minims) contains approximately 0.02 gm. or ⅓ grain; 0.5 c.c. (8 minims) contains 0.01 gm. or ⅙ grain and is usually the first dose for adults; if well borne, subsequent doses may be of 0.8 c.c. (10 minims) containing 0.015 gm. or ¼ grain daily for 20 to 30 injections. It is not necessary to heat the mixture for sterilization since the succinimid is bactericidal in this concentration. The preparation may be kept in a rubber-capped bottle which is very convenient because graded doses may be removed as required, or it may be dispensed in individual ampules of 1 c.c. each. The *succinimid* may be also dispensed in a vegetable oil and injected once a week; I believe this gives less pain and is frequently more convenient for the patient. The dose, however, may be larger; I have employed the following formula with satisfactory results:

℞	Hydrarg. succinimid	6.0 gm. (gr. 100)
	Butyn	0.5 gm. (gr. vii)
	Ol. amyd. exp	100.0 c.c. (f ℥iiiss)

Sterilization by heat is not required. The mixture may be kept in a rubber capped bottle or dispensed in 1 c.c. ampules. The adult dose is 1 c.c. (16 minims) containing 1 grain (0.06 gm.) per week; the dose for children is 0.2 to 0.5 c.c. once a week. If bi-weekly injections are given the dose should be one half these amounts.

When the *bichlorid* is employed the following formula may be used:

℞	Hydrarg. chloridi corrosiv	0.5 gm. (gr. viii)
	Sodii chloridi	1.0 gm. (gr. xvi)
	Butyn	0.5 gm. (gr. vii)
	Aq. sterilat	100.0 c.c. (f ℥iiiss)

Heating for sterilization is unnecessary because of the powerful germicidal activity of the bichlorid. The dose for an adult is 1 c.c. (16 minims) which contains 0.005 gm. or about $\frac{1}{12}$ th grain, each day for a series of 20 to 30 injections.

A better plan is to administer bichlorid in oil because the absorption is slower and there is less pain: the injections may be given once or twice a week and are therefore frequently more convenient for patients than daily injections. The dose, however, may be larger as follows:

℞	Hydrarg. chloridi corrosiv	3.0 gm. (gr. xiv)
	Butyn	0.5 gm. (gr. vii)
	Ol. amyd. exp	100.0 c.c. (f ℥iiiss)

The ordinary adult dose is 1 c.c. (16 minims) which contains 0.03 gm. or ½ grain once a week; if bi-weekly injections are given the dose is 0.5 c.c. (8 minims) which contains 0.015 gm. or ¼ grain. For infants the dose is 0.2 c.c. (3 minims) to 0.5 c.c. (8 minims) once a week which contains $\frac{1}{10}$th gr. (0.006 gm.) to ¼ grain (0.015 gm.).

The *benzoate* of mercury is also widely employed; it is not readily soluble in water but dissolves upon the addition of sodium chlorid. The following formula is quite satisfactory:

℞	Hydrarg. benzoat	2.0 gm. (gr. xxx)
	Sodii chloridi	2.5 gm. (gr. xl)
	Butyn	0.5 gm. (gr. vii)
	Aq. sterilat	100.0 c.c. (f ℥iiiss)

Sterilization by heat is not required since the solution is bactericidal. The solution may be dispensed in a rubber-capped vial or in 1 c.c. ampules. Each cubic centimeter (16 minims) contains 0.02 gm. or ⅓ grain; the usual daily dose is 0.5 c.c. (8 minims) containing 0.01 gm. or ⅙th grain.

The benzoate may be dispensed in oil for injection once or twice a week; this preparation is also a little less painful:

℞ Hydrarg. benz	6.0 gm.	(gr. 100)
Butyn	0.5 gm.	(gr. vii)
Ol. amyd. exp	100.0 c.c.	(f℥iiiss)

The preparation need not be heated for sterilization as the benzoate is bactericidal. It may be dispensed in a rubber-capped bottle or in 1 c.c. ampules. The adult dose is 1 c.c. (16 minims) containing 0.06 gm. or 1 grain once a week or 0.5 c.c. (½ grain) twice a week.

Preparations, Doses and Methods of Administration of the Insoluble Salts.—Many of the old formulas for the insoluble salts of mercury employed paraffin oil but it is now known that this vehicle is not well absorbed and tends to produce nodosities called "paraffinomas" as recently described by Mook and Wander,[8] Stokes and School,[9] Sutton[10] and others. Vegetable oils are to be preferred such as the expressed oil of almonds, olive oil, cotton seed oil or palmitin; these are saponified in the tissues and more rapidly absorbed with the result that nodosities are now quite uncommon, although they may still develop from the irritation produced by mercury or in the form of traumatic gummas.

Of the insoluble salts of mercury, the *salicylate* is undoubtedly the most popular; I have employed the following formula with success:

℞ Hydrarg. salicyl	6.0 gm.	(gr. 100)
Butyn	0.5 gm.	(gr. vii)
Ol amyd. exp	100.0 c.c.	(f℥iiiss)

Sterilization by heating is not required since the salicylate in this concentration is bactericidal even though insoluble. The mixture may be dispensed in a stock bottle or in ampules but requires thorough shaking to suspend the drug before injection. A heavier base like palmitin may be employed if desired. The dose is 1 c.c. (16 minims) containing 0.06 gm. or 1 grain, once per week or 10 days for six to ten injections. Children are given less in proportion to weight.

Calomel suspensions are also widely employed being more therapeutically active but also more painful; sublimed rather than precipitated calomel is preferable in making up the following formula:

℞ Hydrarg. chlor. mit	5.0 gm.	(gr. 75)
Butyn	0.5 gm.	(gr. vii)
Ol. amyd. exp	100.0 c.c.	(f℥iiiss)

Sterilization by heating is not required since the suspension is highly bactericidal. The mixture may be dispensed in a bottle or in individual ampules, but should be well shaken before injection to secure an even suspension and uniform dose. The usual adult dose is 1 c.c. (16 minims) containing 0.05 gm. or $\frac{9}{10}$th grain once a week or every 10 days for not more than four injections in succession. Children may be injected with smaller amounts proportionate to body weight.

Cole, Littman and Sollmann[10a] have advocated the following formula for either the salicylate or calomel:

Anhydrous lanolin	40 gm.
Distilled water	10 c.c.
Sweet almond oil	150 c.c.
Calomel or mercuric salicylate	29 gm.
Phenol or creosote	20 c.c.
Camphor	40 gm.

The dose of 1 c.c. equals 0.09 or 1½ grains of calomel or mercuric salicylate and is injected intramuscularly once a week.

Metallic mercury in suspension is also widely employed being well known as *gray oil* or *oleum cinereum* (B. P. C.) containing 40 per cent. mercury in very finely divided particles. This strength however, is too high for accurate dosage and requires dilution. If made up from oleum cinereum the mixture may be as follows:

℞ Ol. cinerei	15.0 gm.
Butyn	0.5 gm.
Ol. amyd. exp. q.s	100.0 c.c.

Each cubic centimeter of this mixture (16 minims) contains 0.06 gm. or 1 grain of metallic mercury which is the usual adult dose once a week or once every ten days for a series of six to ten injections. The mixture does not require heating for sterilization but must be well shaken before injection to secure an even suspension and correct dose.

The preparation may be prepared direct from purified mercury according to the following formula, and employed in exactly the same manner:

℞	Hydrarg. pur.	6.0 gm.
	Butyn.	0.5 gm.
	Ol. amyd. exp. q.s.	100.0 c.c.

The dose for an adult is ordinarily 1 c.c. (16 minims) containing 0.06 gm. or 1 grain of metallic mercury, once a week or every ten days for six to ten injections.

Method of Intravenous Injection.—The intravenous injection of mercurial salts was introduced by Bacelli in 1893, but has since acquired but relatively few advocates as a route of administration in the treatment of syphilis, insofar, at least, as the ordinary compounds are concerned. Recently interest in the subject has been renewed since the introduction of flumerin and mercurosal for intravenous medication. Colloidal suspensions of calomel and of metallic mercury have also been advocated and, as stated in Chapter XXX, I have employed mixtures of mercurophen and neoarsphenamin for several years.

Advantages and Disadvantages.—The chief advantage is the rapidity of mercurialization which may be demanded in the treatment of grave cases of syphilis to whom arsphenamin and its substitutes cannot be given on account of intolerance or hypersensitiveness. By throwing the medicament directly into the blood no time is lost in absorption. This, however, may be likewise a disadvantage by reason of rapid elimination in which case a portion of the compound may be eliminated before dissociation or ionization occurs and therefore without exerting therapeutic effects. Additional advantages are mathematically correct dosage and the absence of pain and disability.

However, these injections are not always free of pain and especially if rapidly dissociable compounds like the bichlorid are injected. Phlebitis and thrombosis are not infrequent when this salt is injected although less common in the case of the succinimid and relatively rare with flumerin, mercurosal, mercurophen and colloidal suspensions of calomel and metallic mercury. When bichlorid is accidentally injected perivascularly rather severe reactions may follow; perivascular injections of the last mentioned compounds produce much less reaction.

Intravenous injections may produce some immediate reactions of nausea and vomiting and are more likely to produce polyuria and gastro-intestinal disturbances including salivation and stomatitis, than intramuscular injections. The incidence of these, however, can be reduced by injecting smaller doses and by increasing the intervals between injections. An additional disadvantage for many patients is the frequency of injections; they should be given at least every two to three days for at least six injections, which may be very annoying when several series of injections are required.

In my opinion, therefore, the only real indications for intravenous injections of mercury are two, namely (*a*) to avoid local pain since it is possible to give these without producing phlebitis and thrombosis, and (*b*) to secure more rapid effects than possible from other routes of administration. An additional advantage is the possibility of injecting mixtures of neoarsphenamin or sulpharsphenamin with mercury at the same time with the same syringe; for this purpose, however, only mercurophen or flumerin may be used since the bichlorid, succinimid, mercurosal and other salts are precipitated with more or less rapidity.

Technic of Administration.—Intravenous injections of mercurial compounds are given with a syringe fitted with a No. 22 needle as described on page 831.

Preparations, Doses and Methods of Administration.—The *bichlorid of mercury* has probably been used more frequently than other compounds, but is the least desirable of all from the standpoint of producing phlebitis and thrombosis as well as general ill effects. Bastron[11] has recently advocated doses of $\frac{1}{10}$th grain every three days, gradually increased until as much as $\frac{1}{2}$ grain is given robust adult men. As soon as slight soreness of the gums is produced, the dose is held constant, but the intervals increased to one or two injections a week, a course being at least of six weeks duration. It is convenient to employ a stock 1:1000 solution; 1 c.c. of this contains 0.001 gm. and 6 c.c. contains 0.006 gm. or $\frac{1}{10}$th grain, which is the first dose. Subsequent doses, therefore, are easily increased although I doubt if more than 15 c.c. (0.015 gm. or $\frac{1}{4}$ grain) should ever be exceeded; the injections may be given every three to five days with a close watch for salivation and irritation of the kidneys.

Bastron has also advocated the intravenous injection of bichlorid suspended in serum (mercurialized serum) as being a means for reducing the incidence of phlebitis and thrombosis, but this modification is by no means free of these effects. For these injections human serum is much to be preferred to preparations of horse serum, because the latter tends to produce sensitization and serum sickness. The serum of the patient or the sterile serum of some other human being belonging to the same blood group may be employed and the mixtures kept in sealed ampules ready for administration. For preparing the serum one may add to 1 to 5 c.c. the dose of bichlorid: for a $\frac{1}{10}$th grain dose this may be 0.6 c.c. of a 1:100 solution of bichlorid and for the $\frac{1}{4}$ grain dose, 1.5 c.c. of a 1:100 solution. The mixtures become cloudy, but gradually clear if an excess of serum is employed.

In my experience the *succinimid* is much to be preferred to bichlorid. It is less toxic and much less likely to produce phlebitis. I employ a stock 1:1000 solution and begin with 6 c.c. (0.006 gm. or $\frac{1}{10}$th grain); the injections are given twice a week and gradually increased but never beyond 15 c.c. ($\frac{1}{4}$ grain) at one time.

Flumerin is injected in the form of 2-per cent. solutions in sterile water or saline and these are stable for several days. The dose advised by White and his colleagues has been 0.003 to 0.005 gm. per kilo every two or three days. From my experience with the drug I would advise not more than 0.003 gm. every two days for at least six injections as a course, unless signs of intolerance appear. For an adult of 135 to 150 pounds this dose would be from 10 to 15 c.c. of the 2-per cent. solution or 20 to 30 c.c. of a 1-per cent. solution, the latter being my choice. Marked variations in individual tolerance for flumerin have been noted and since these are not always predictable, patients should be carefully watched for toxic symptoms including routine examinations of the urine.

Mercurosal is usually given in dose of 0.1 gm. freshly dissolved in 5 to 10 c.c. of sterile water or saline solution; my preference is for 20 c.c. of saline solution. The injections are given bi-weekly or every two to three days for at least six injections as a course, unless signs of intolerance appear. The drug is dispensed in the form of a powder in ampules and the solutions are prepared as required just before administration.

The insoluble compounds like colloidal suspensions of *calomel* and of the *metal* are not widely employed in this country. Their possible advantages as compared with intravenous injections of the soluble salts are somewhat slower dissociation, slower elimination, greater freedom from toxic reactions and slightly more prolonged therapeutic effects; pulmonary embolism does not occur when suitable preparations are employed and irritation of the veins is uncommon when the compounds are properly injected. The dose of calomel is ordinarily 0.01 to 0.03 gm. for an adult, corresponding to $\frac{1}{6}$th to $\frac{1}{2}$ grain, every four or five days until ten to twelve injections have been given, unless signs of intolerance and renal irritation develop. Podesta[12] has recently advocated suspensions of calomel in concentrated glucose solution for intravenous injection, but I believe that preference is to be given the soluble compounds. A similar preparation of metallic mercury designated as "lueside" or "mercudol" has been reported upon unfavorably by Cole and his associates.[12a]

Combined Intravenous Injections of Arsenical and Mercurial Compounds.—As stated in Chapter XXX, the addition of a small dose of a compatible mercurial compound to solutions of neoarsphenamin appear to increase trypanocidal and spirocheticidal properties, the mercury acting as a catalyzer or activator of the spirocheticidal activities of the arsenic. The mercury itself produces curative effects in addition to those of the arsenic, if the dose is sufficiently large, as in Linsser's method of the treatment of syphilis.

During the past four years, I have injected mixtures of mercurophen and neoarsphenamin in the treatment of syphilis without ill effects and, I believe, with good therapeutic results. My method is to dissolve 0.9 gm. of neoarsphenamin in 5 or 10 c.c. of water and add 15 c.c. of a 1:1000 stock solution of mercurophen. The mixture, which sometimes becomes slightly opalescent, is filtered and injected at once with a syringe once or twice

a week. The dose of mercurophen is 0.015 gm. or ¼ grain, which is well borne and produces on phlebitis or thrombosis. Sulpharsphenamin in dose of 0.4 to 0.6 gm. may be used in exactly the same manner. Alkaline solutions of arsphenamin (disodium salt) are also compatible and I have many times added 15 c.c. of 1:1000 mercurophen to the solution in the cylinder and injected both intravenously without any ill effects whatsoever from the mercury. The succinimid of mercury and mercurosal cannot be used with either neoarsphenamin or sulpharsphenamin, although mercurosal can be used with arsphenamin (disodium salt) if the mixture is injected at once. Flumerin in dose of 5 to 10 c.c. of 2-per cent. solution may be used with any of the three arsenicals in the same manner; the dose is reduced in order to avoid a double reaction from the two drugs. Bichlorid and succinimid, however, cannot be used because of the rapid production of greenish black solutions due to precipitation of mercury, unless such are desired as in Linsser's method employing the former (see page 353).

Method of Intraspinal Injection.—Various methods have been advocated for the treatment of neurosyphilis by intraspinal injections of mercury since Ravaut[13] in 1913 first injected two drops of 0.1- to 1-per cent. solutions of bichlorid and cyanid of mercury. It was soon found, however, that these injections produced considerable irritation and had to be adandoned. I have found that intraspinal injections of mercurophen, bichlorid and mercurochrome in rabbits in doses as small as 0.001 gm. per kilo frequently produce marked irritation of the meninges with congestion and hemorrhages.

In 1914 Byrnes,[14] however, greatly improved the technic by first mixing bichlorid with serum to form the albuminate before injection. This method may be conducted as follows:

1. Remove 50 c.c. of blood from the patient and after coagulation draw off the serum. Centrifuge if necessary to remove all corpuscles. The sterile serum of some other person may be used instead. More recently, sterile horse serum has been employed, but this is objectionable from the standpoint of sensitizing the patient and producing serum sickness, either as a result of subsequent intraspinal injections or whenever horse serum is administered for prophylactic or therapeutic purposes as in the administration of diphtheria and tetanus antitoxin.
2. Add to 20 c.c. of the serum $\frac{1}{50}$th to $\frac{1}{25}$th grain (0.0013 to 0.0026 gm.) of bichlorid. The smaller dose should always be employed at first and the amount increased only in subsequent injections. The dose of $\frac{1}{50}$th grain is secured by adding 1.3 c.c. of a 1:1000 solution of bichlorid in water; the $\frac{1}{25}$th grain dose is secured by adding 2.6 c.c. of the 1:1000 solution.
3. Mix and place in a water bath at 56°C. for thirty minutes.
4. Conduct spinal puncture; collect 10 to 20 c.c. of spinal fluid in the barrel of the gravity apparatus, add the mercurialized serum and inject the mixture by gravity as described on page 858.

CHAPTER LXIV

TECHNIC OF VARIOUS METHODS FOR THE ADMINISTRATION OF BISMUTH IN THE TREATMENT OF SYPHILIS

During the past few years a very large number of new bismuth preparations have been described and advocated for the treatment of syphilis, but with few exceptions these compounds have not been subjected to thorough toxicity and spirocheticidal studies; indeed, the deplorable freedom and frequency with which new drugs are administered to human beings, before adequate preliminary investigations have been made on the lower animals, is no where better shown than in the list of arsenicals, mercurial and bismuth preparations fostered upon the medical profession by commercial laboratories during the past five years and especially in France and Germany. In a general manner it may be stated that the curative activities of all the bismuth preparations are about the same when administered on an equivalent bismuth basis, which varies from 16 per cent. in "bicreol" to 96 per cent. in "neotrepol."

At the present time bismuth is administered in the treatment of syphilis almost entirely by intramuscular injection. The advantages and disadvantages of intravenous, intramuscular and oral administration are almost identical with those pertaining to the administration of mercury discussed in the preceding chapter and for the sake of brevity these need not be reviewed with detail in this chapter.

The toxicology of bismuth has been reviewed in Chapter LV and the physician should familiarize himself with the main effects before administering bismuth in the treatment of syphilis. In a broad and general manner the toxic effects of siderosis, salivation, stomatitis, etc., are quite similar to those of mercury but usually of milder degree. The pain and nodosities of intramuscular injections of suspensions in oil are much less than follows injections of the salicylate or other mercurial salts.

Intravenous Administration of Bismuth in the Treatment of Syphilis.—Several of these new compounds of bismuth are designed for intravenous injection; some are colloidal suspensions, while others are administered in water or glucose solutions. In Germany intravenous injections of bismuth hydroxid, in colloidal suspension, in dose of 0.010 gm. (1/6th grain) for an adult, is being widely employed. I have had only a limited experience with them in experimental studies and as stated in Chapter LV the toxic effects produced by bismuth may be very much intensified as compared with intramuscular injections.

It would appear that the only indication and excuse for intravenous injections are grave cases of syphilis to whom arsphenamin and its substitutes cannot be given because of toxic reactions but which require a more active spirocheticidal drug than the soluble mercurials. I have repeatedly administered 0.01 gm. (1/6th grain) of potassium tartrobismuthate dissolved in 10 c.c. of saline solution and sterilized by heating, without ill effects; this amount is 10 to 20 times less than the usual dose by intramuscular injection and I am able to recommend it when intravenous injections are required. In rabbits a series of twelve to thirty daily injections in dose of 0.0002 gm. per kilo, which corresponds to approximately 0.01 gm. per 70 kilograms or 145 pounds, were

without discernible clinical reactions and produced no histological changes in the kidneys, liver and other internal organs; I believe, therefore, that this dose (1/6th grain) for adults is just as safe for intravenous administration in the treatment of syphilis as the bichlorid, succinimid, cyanid or other soluble mercurial compounds. My practice is to prepare the solution as follows: Dissolve 0.2 gm. of potassium tartrobismuthate in 19 c.c. of saline solution; heat at 70°C. for thirty minutes, cool and add 1 c.c. of 5 per cent. phenol. Culture and if sterile dispense in 1 c.c. amounts in 20 sterile ampules. For administration dilute 1 c.c. with 9 c.c. of saline solution in a sterile syringe and inject slowly with a No. 22 needle as described in Chapter LIX. This dose is, therefore, 0.01 gm. or 1/6th grain; phlebitis is not produced. The injections are given every two to three days for a series of ten to twelve doses.

Intramuscular Administration of Bismuth in the Treatment of Syphilis. Bismuth is almost always administered by intramuscular injections in the treatment of syphilis. Suspensions in sterile almond oil are much less painful and better borne than solutions in water or glucose.

The quartenary salt sodium and potassium tartrobismuthate occurs in two forms, the soluble and insoluble. Potassium tartrobismuthate is soluble and may be administered in solution or suspended in oil.

The dose of either compound may be 0.1 or 0.2 gm. for adults every 3 or 4 days until 2 to 3 grams have been given (20 to 30 injections of the 0.1 gm. dose or 10 to 15 injections of the 0.2 gm. dose).

Solutions may be prepared as follows: Dissolve 4 gm. of potassium tartrobismuthate or sodium and potassium tartrobismuthate in 17 c.c. of sterile saline solution or water; heat at 70°C. for sixty minutes; add 1 c.c. of 2-per cent. butyn in sterile water and 1 c.c. of 5-per cent. phenol. Culture and if sterile dispense in 1 c.c. amounts in 20 sterile ampules. Each cubic centimeter contains 0.2 gm. of drug and the butyn prevents immediate pain after injection.

Suspensions may be prepared as follows: suspend 4 gm. of potassium tartrobismuthate or sodium and potassium tartrobismuthate and 0.04 gm. of butyn in 40 c.c. of almond oil. The drugs should be gradually and thoroughly rubbed up with a small amount of oil until an even emulsion is secured when the balance of the oil may be gradually added.

Sterilize by autoclaving at 10 pounds for at least 30 minutes and culture. If sterile dispense in 2 c.c. amounts in sterile ampules which thereby contain 0.2 gm. each. Ampules with long narrow necks should not be used as the drug tends to settle in them unless constantly kept in an upright position, and require a great deal of shaking to obtain all in suspension preliminary to injection. Sterilization may be done after the ampules have been prepared instead of in bulk.

The injections are given into the gluteal muscles as described on page 841; they are almost painless.

Oral Administration of Bismuth in the Treatment of Syphilis.—As far as I am aware, bismuth has not been employed by oral administration in the treatment of syphilis. During the past two years, however, I have administered potassium tartrobismuthate and sodium tartrobismuthate internally in the treatment of chronic syphilis with tertiary skin and mucous membrane lesions, with the general result that toxic or untoward effects were not produced while the lesions were gradually dissipated. My impression, however, is that the effects were not as prompt as obtained from the internal administration of the soluble mercurials.

I have given rabbits as many as fifty consecutive daily doses of 0.02 gm. of potassium tartrobismuthate per kilo by stomach tube without producing

any histological changes in the kidneys, liver or other organs; this dose corresponded to 1.2 gm. or 20 grains per 60 kilograms and was 4 times more per body weight than given to cases of syphilis which was 0.1 gm. three times a day after meals, corresponding to 0.3 gm. or approximately 5 grains daily. The drug was dispensed both in capsules and in solution. The taste is metallic and disagreeable, but not more so than bichlorid of mercury. Potassium iodid and sodium iodid are incompatible; the former produces an immediate white precipitate while the latter forms a precipitate more slowly. The following formula is generally well borne:

Potass. tartrobismuth..... 6 gm. (ʒiss)
Aq. destil.
Syr. sarsaparil.....āā 100 c.c. (fʒvi)

One teaspoonful (approximately 2 grains or 0.12 gm.) is given three times a day after meals.

Other Methods for the Administration of Bismuth in the Treatment of Syphilis.—*Subcutaneous injections* of the soluble salts have no advantage over intramuscular injections and they usually produce more severe local reactions. Klauder has employed *inunctions* of bismuth trioxid in experimental syphilis of rabbits, but found that its spirocheticidal effects were feeble and inferior to mercury. I do not know of any other work on this route of administration. *Intraspinal injections* of bismuthized serum have not been reported upon and I have not employed them in my own practice.

CHAPTER LXV

TECHNIC OF VARIOUS METHODS FOR THE ADMINISTRATION OF THE IODIDS IN THE TREATMENT OF SYPHILIS

Since the iodids are absorbed so rapidly from the gastrointestinal canal, they are usually administered by *ingestion*. Within recent years, however, there has been an increasing tendency to administer sodium iodid by *intravenous injection*, and when a very high concentration is desired in the blood and spinal fluid for the treatment of grave cases of neurosyphilis, this method of administration has advantages. The *subcutaneous injection* of the inorganic iodids, like potassium iodid and sodium iodid, has been abandoned, because of the pain and severe local reactions produced; but combinations of iodin with oil (*iodipin*) are less painful and sometimes administered by this route. *Rectal injections* of the inorganic iodids are also employed and may be useful under certain conditions to be shortly reviewed.

Method of Ingestion. *Choice of Iodid.*—Since the iodids are absorbed so rapidly from the gastro-intestinal tract they are usually administered by ingestion. Potassium iodid is the time honored drug and was the favorite of Fournier. Hutchinson was fond of prescribing the three iodids of potassium, sodium and ammonium together in the one solution, believing that these and especially the addition of ammonium, reduced irritation. Sodium iodid is regarded by some authors as better tolerated than iodid of potassium, less irritating and less depressing. I believe it is sometimes better borne than potassium iodid, but it is, on the other hand, slightly less therapeutically active. Lipoiodin, pepto-iodin, diluted tincture of iodin, iodoform and a host of organic combinations have been advocated, but potassium iodid, sodium iodid and pepto-iodin are sufficient for the treatment of the majority

of cases of syphilis. Combinations with peptone, etc., are said to be less irritating to the stomach, probably because dissociation of the iodid ion is less rapid than in the case of the inorganic iodids; but in difficult cases my preference at present is for combinations with oil (*iodipin*) or the fatty acids, as *sajodin*, which are dissociated and eliminated less rapidly. Sajodin is also tasteless and less irritating which may be an advantage in some cases.

The syrup of ferrous iodid or the syrup of hydriodic acid may be chosen for infants, but the amounts of iodid contained are very small and I believe preference is to be given solutions of potassium or sodium iodid.

Dosage.—When first administered, small doses of the iodids are generally as effective as large doses, but sometimes a dose of 2 or 3 grains three times a day produces ill effects when 10 grains or more three times a day are better borne. Fournier states that for an adult man of good constitution and average strength, the average dose is 45 grains a day; for an adult woman in the same condition, 30 grains a day. He regarded doses smaller than these as insufficient, if not always, at least in the great majority of cases, and held that daily doses of 4 to 15 grains were quite incapable of producing the therapeutic action expected from iodid. It was his belief that the height of therapeutic activity varied from 30 to 60 grains as a daily dose, and that larger doses, while useful and indicated in certain cases, were useless in the majority. For example, in grave cases of syphilis as gumma of the palate on the verge of perforation, in neurosyphils, in severe phagedenic ulcerations, or in chronic refractory lesions, Fournier believed in large doses, but never in excess of 150 grains a day, holding that if this dose failed, so also would larger amounts.

Plan of Administration.—The iodids are of most use in the treatment of chronic syphilis, either latent or active, and I believe should be given along with intravenous injections of arsphenamin or one of its substitutes, mercury or bismuth. The effects of iodids appear to "wear off" as administration is continued, and for this reason they should be used intermittently rather than continously and in ascending doses, a maximum of 60 to 90 grains per day, however, being seldom exceeded.

It is my custom to prescribe 5 grains of potassium iodid three times a day for the first week, 10 grains three times a day for the second week and 15 grains three times a day for the third week if well borne. As a general rule, this dose need not be raised, although in some cases presenting gummas the dose is raised each week until 30 grains are being taken three times a day. I rarely exceed this dose and the administrations are kept up throughout the course of injections of arsphenamin or neoarsphenamin, etc., mercury or bismuth, which is usually twelve weeks. For the purpose of raising the dose in this manner, the usual solution of potassium iodid is prescribed:

Potass. iodidi	100.0 gm.
Aq. destil.	q.s. ad 100.0 c.c.

Each drop contains 1 grain and the patient is advised to take 5 drops (with a dropper), 10 drops, etc., as the case may be.

As a general rule, I advise taking the iodid about one half to a quarter of an hour *before* meals, *well diluted* with water, milk or ginger-ale, etc.

If signs of gastric irritation appear, it is advantageous to substitute sodium iodid in the same manner.

If a constant or fixed dose is being given and the taste is objectionable, it is advantageous to use Ricord's old prescription:

Potass. iodidi	1.5 gm.(℥iv)
Syr. corticis aurantii	200 c.c.(f℥vi)

This mixture may be given in dose of 2 teaspoonfuls (10 grains) three times a day in water or one teaspoonful (5 grains) three times a day.

Inasmuch as it is sometimes very inconvenient for a patient to take iodid three times a day, I frequently permit the whole dose of 30 to 45 grains once a day just before the main meal; if 60 grains or more per day are being taken, it is well, under these circumstances, to split the dose into two administrations rather than taking all at one time.

If signs of intolerance appear as persistent rhinorrhea, "tightness of the jaws," acne, etc., it is well to stop the administrations until these disappear and then resume with about one-half or three-fourths of the dose producing these effects.

The dose of *sajodin* (the monoiodobehenate of calcium) is 1 to 3 gm. (15–45 grains) daily in powders, as the preparation is a colorless and tasteless powder. The dose of *iodipin* is 4–8 c.c. (1–2 drs.) three times a day after meals.

Method of Intravenous Injection.—Within recent years the intravenous injection of sodium iodid has been used with increasing frequency and especially since the report by Howard[1] of its success in the treatment of a very difficult case of laryngeal syphilis to whom a series of 125 injections totalling 26,013 grains or about 3¾ avoirdupois pounds of sodium iodid had been given; Farnell[2] and others have also reported good results with this method of administration.

Indications.—As previously stated the oral administration of potassium or sodium iodid fulfills the requirements of iodid therapy in the majority of cases of syphilis, but as stated by Howard, intravenous injections are to be preferred and are indicated under certain conditions, briefly summarized as follows:

1. Whenever the full iodid effects are required, that is to say, whenever extra high concentrations are required in the blood and cerebrospinal fluid for the treatment of grave cases of tertiary syphilis as tabes, paresis, aortitis, cirrhosis of the liver, etc.
2. For the treatment of patients unable to swallow.
3. When large doses by mouth are ineffective and symptoms are progressive.
4. When signs of iodidism develop from oral administration before the desired results are obtained, that is to say, when signs of intolerance from ingestion are present, intravenous injections are sometimes well borne and deserving of trial.

The only *contra-indication* that I know of is hypersensitiveness to iodid which usually manifests itself as edema of the glottis as the most severe and dangerous lesion. Whenever possible, therefore, it is well in the case of new patients, to first administer a few doses by ingestion before intravenous injections are given, in order to make sure that hypersensitiveness is not present; fortunately, the condition is quite rare.

Dosage and Method of Administration.—Sodium iodid is to be preferred because of the low toxicity of the sodium ion. As a general rule sterile 10-per cent. solutions in water are employed. The water should be freshly distilled in order to remove bacterial and other proteins; each 10 c.c. carries 1 gram or 15 grains of iodid. The solution may be sterilized by boiling for 5 to 10 minutes without dissociation; when properly sealed, it keeps for long periods of time.

The usual dose is 1 to 2 grams (10 to 20 c.c. of 10-per cent. solution) daily or two to three times a week. The injections are given with a syringe as described on page 831. Larger doses however, may be given up to 100 c.c. or 10 grams, by means of gravity injection. Doses of this size should not be repeated oftener than twice a week except in unusually severe cases.

Combined Injections with Neoarsphenamin and Mercurials.—I sometimes inject neoarsphenamin and sodium iodid together in the same syringe twice weekly, the dose of 0.6 to 0.9 gm. of neoarsphenamin being dissolved in 5 to 10 c.c. of sterile water and mixed with 10 to 20 c.c. of the sterile 10-per cent. solution of sodium iodid. A series of twelve combined injections of this kind are given as a course (6 weeks) and at the same time sodium or potassium iodid may be given by mouth to maintain the effects of the injections.

In some cases I have also combined mercurophen in dose of 5 c.c. of 1:500 solution (1/6th grain or 0.01 gm.) or flumerin in dose of 10 c.c. of 1:50 solution (4 grains or 0.2 gm.) with 10 to 20 c.c. of 10-per cent. sodium iodid; these combinations are well borne. I have likewise given a large number of combined injections of 0.6 gm. neoarsphenamin dissolved in 10 c.c. of 10-per cent. sodium iodid solution to which is added 5 c.c. of 1:500 mercurophen or 10 c.c. of 1:50 solution of flumerin. These mixtures are slightly opalescent in the case of mercurophen, but perfectly clear in the case of flumerin and are well borne. I believe that combination therapy of this kind yields best results in the treatment of some selected cases of tertiary syphilis, but in the majority of cases the iodids are given by ingestion, while the neoarsphenamin and mercurials are administered separately.

Method of Subcutaneous Injection.—Subcutaneous injections of potassium iodid or sodium iodid are usually quite painful and large doses may produce sloughing. Intravenous injections, therefore, are very much more preferable. However, if these cannot be given and ingestion is impossible, subcutaneous injections of *iodipin* (an iodin addition product of sesame oil) may be injected in dose of 2 to 6 c.c. of 25-per cent. strength; this produces much less irritation. If the inorganic iodids are injected preference is to be given sodium iodid in dose of 1 c.c. of a 50-per cent. solution in water sterilized by boiling (0.5 gm. or about 8 grains).

Method of Rectal Injection.—This method is only required in exceptional cases when oral and intravenous administrations cannot be given. A simple cleansing enema is first given, followed by the high injection of 5 grams (77 grains) of sodium iodid or potassium iodid dissolved in 6 to 8 ounces of water to which is added 5 drops of tincture of opium. Injections are given once daily, but stopped when signs of rectal irritation develop. Larger doses are possible as up to 15 grams per day. More dilute solutions may be introduced by the drop method, but I believe the former is to be preferred when the dose does not exceed 5 grams.

Other Methods of Administration.—Lawson[3] has injected sodium iodid intraspinally, in the treatment of three cases of paresis, along with the administration of neoarsphenamin and mercury. The iodid was first given in small doses and gradually increased to 30 c.c. of a 0.6-per cent. solution (0.18 gm. or 3 grains). There was no pain or bladder disturbance, but there seemed to be an increased spasticity and temporary increase of mental confusion. There was little improvement in the spinal fluid changes, but all patients improved clinically. Excretion of the iodid appeared to be slower than when given by ingestion to normal individuals. This method, however, does not appear to be indicated in the treatment of syphilis since Osborne has shown that iodin is to be found in the cerebrospinal fluid after the ingestion of the iodids and particularly after the intravenous injection of large doses of sodium iodid. Furthermore, the only excuse for intraspinal injections in syphilis is the possibility of direct spirocheticidal effects and these small doses of iodid are certainly without this action, whereas the proteolytic or dissolving action of the iodids upon exudates and fibrous tissue can surely be better obtained by the administration of large doses by ingestion or intravenous injection.

Since the iodids are very poorly absorbed through the skin and since they are very feeble in spirocheticidal activity, it is irrational to use the liniment and ointment of potassium iodid for the treatment of syphilis.

PART X

PROPHYLAXIS, GENERAL, SPECIFIC AND NON-SPECIFIC TREATMENT OF SYPHILIS

CHAPTER LXVI

GENERAL CONSIDERATIONS IN THE TREATMENT OF SYPHILIS

The modern treatment of syphilis includes not only the chemotherapy of this disease, but general, hygienic and other forms of treatment as well. In experimental syphilis of the lower animals we may treat the lesion or the disease, but with human subjects we must treat the patient, which requires a broad and comprehensive knowledge of general therapeutics as well as a special knowledge of syphilis. As stated by Fournier,[1] "to treat a syphilitic lesion it is sufficient to make the diagnosis and apply the remedy which experience has shown to be best under the circumstances; while the treatment of syphilis, looked upon not as a lesion, but as a disease, is much more comprehensive and complex. The latter includes a number of most different questions, all difficult, controvertible and controverted. It even includes general questions of major importance, on which may depend the success or failure of treatment." Again "to treat syphilis is not only to attack and cure the manifestations of a day, or even of a period; it is also and especially to attack the disease as a whole, to attack it when patent and latent; to lay hold of its primary cause, the origin of its actual and future determinations. It is to institute, with this object, a treatment of long duration—almost chronic—which alone is sufficient to realize *preventive* effects—that is, to protect the patient against the future, and to safeguard not only himself, but his posterity."

Since these words were written by the great French syphilologist, epoch making discoveries during the past twenty years have confirmed their truth and especially in the treatment of chronic syphilis. Indeed, Fournier did not live long enough to realize their full significance, since the discovery of *Spirochæta pallida*, along with methods for its detection in the tissues and with the discovery of the complement-fixation reaction, has shown how widespread the infection may become in the tissues and organs of individual cases and how difficult it may be to bring about cure in the sense of complete destruction of the parasites. Fournier clearly realized and taught that the dissipation of obvious lesions did not necessarily mean the cure of the disease and modern discoveries have amply confirmed his clinical opinions.

Modern Treatment of Syphilis an Example for Future Chemotherapeutic Investigation.—Our knowledge of syphilis is still far from complete, but in no other disease known to mankind have such wonderful discoveries been made in the etiology, pathology, immunity and treatment as have been made in syphilis during the past twenty years. Its cause, *Spirochæta pallida*, was

discovered by Schaudinn in 1905 and this was followed within a short time by the development of methods for the detection of the parasite in the secretions of the chancre, thereby opening up methods for the immediate diagnosis and treatment of the disease in its earliest stage instead of waiting for confirmation by the appearance of the secondary lesions of generalized infection. Within a year after this epoch-making discovery, the first application of Bordet's and Gengou's phenomenon of complement fixation for the diagnosis of disease was made by Wassermann and his colleagues and independently by Detre, in the diagnosis of tuberculosis and syphilis, and since then this serological reaction has been developed into a diagnostic method for syphilis without parallel today as a practical and valuable procedure for the diagnosis of disease and as a means for the control or check upon its treatment. And just about four years later Ehrlich, Bertheim and Hata discovered salvarsan for the treatment of syphilis in a series of researches without comparison in brilliance and fruitful results which put the climax upon this period of remarkable discoveries stretching over a period of but little more than five years from the time of Schaudinn's discovery. As previously stated this remarkable triad of discoveries is without parallel in the history of medicine and since then numerous other discoveries along the paths blazed by Schaudinn, Bordet and Wassermann, Ehrlich and Hata have rendered the diagnosis and treatment of syphilis a lasting testimonial and monument to what may be accomplished by prepared minds and systematic research.

The modern treatment of syphilis will stand as a goal and ideal for future efforts in chemotherapeutic research. The chemotherapy of this disease is a perfect embodiment of the underlying principles and difficulties of research in this field of the art and science of medicine. It has shown us that to prepare new compounds, determine their toxicity for healthy animals and finally their curative activities for an experimentally produced infection, is not sufficient; we must know something of their absorption and elimination, their toxic effects in the diseased human subject and finally their curative activity as modified by the pathological and immunological changes of disease. The modern treatment of syphilis, and especially of chronic syphilis, is not yet upon a satisfactory basis; more, much more, must be discovered for the successful treatment of chronic syphilis although the treatment of early syphilis by modern chemotherapeutic measures may be regarded as practically a solved problem.

I may repeat, therefore, that the phenomenal progress made in the treatment of syphilis during the past decade has blazed the trail for similar efforts in other diseases and has shown how complicated and laborious may be chemotherapeutic research even under the most favorable circumstances. Experience in the treatment of human syphilis has shown that many and important factors require consideration and solution after the fundamental facts have been established by animal experimentation. And, in passing, it is fitting to pay tribute to the enormous value of animal experimentation in the development of the modern treatment of syphilis, trypanosomiasis and other diseases; a mere glance at the preceeding chapters, summarizing the results of such investigations, is sufficient for indicating the debt we owe legitimate and systematized experiments upon the lower animals. Without animal experimentation salvarsan would not have been discovered and without it future progress in the chemotherapy of disease would not be possible.

Regarding the Standardization of the Treatment of Syphilis.—For several hundred years attempts have been made to standardize, as it were, the treatment of syphilis with mercury or a combination of mercury and the

iodids. Since the discovery of salvarsan and allied compounds, attempts in this direction have been renewed and the medical profession in general has ever been ready to welcome any clear cut and brief directions generally applicable for the treatment of all cases.

But such is not advisable, except possibly in the treatment of early syphilis. We may readily enough standardize a laboratory test but not the treatment of a disease, because of the possibility and probability of so many modifying factors requiring consideration and the necessity for treating the patient rather than a symptom, a lesion or the disease itself. Probably in syphilis we may go further; it is possible to lay down a plan of treatment for the medicinal prophylaxis of the disease generally applicable to all cases and we can express an opinion concerning the minimum amount of treatment for all or, at least, the majority of cases during the first six to twelve months after the appearance of the chancre. The majority of cases of primary syphilis are otherwise healthy individuals, that is, there is not usually present some other disease of sufficient severity to materially alter or influence our set plan of treatment for early syphilis. Likewise we may adhere to a set plan of general treatment, as the search for focal infection with special reference to the teeth and gums, the correction of dietary and hygienic errors, etc. But after the first six to twelve months we should individualize our patients and especially all cases coming under observation in the late stages of the disease regardless of the kind and amount of treatment previously received. Therefore, while we may be justified in expressing an opinion on what should constitute a plan of treatment generally applicable to all cases of syphilis during the first six to twelve months after infection and on what should constitute a minimum amount of treatment at this time, regardless of negative Wassermann reactions and freedom from clinical signs and symptoms, we can hardly generalize treatment beyond this period. For late cases of syphilis we may reach a decision upon what constitutes a "course of treatment" and when an organic arsenical, mercury, bismuth or an iodid compound is indicated singly or in combination, but the size and frequency of the dose, route of administration, number of "courses," intervals of rest from specific medication, general treatment, etc., are factors requiring more or less arrangement for individual cases. If it were possible to eradicate all *Spirochæta pallida* from the tissues of all cases of syphilis with a medicinal compound free and safe from untoward toxic effects, nothing would be easier than the treatment of the disease by rule of thumb. In the first year after the discovery of salvarsan, hopes of this kind were entertained because of its successful accomplishment in experimental infections of the lower animals. But we know to-day that there is no such medicinal available at present; in the treatment of frambesia and very early syphilis with arsphenamin or neoarsphenamin, *magna therapie sterilsans* has come nearest to accomplishment in human disease, but even in these we know that one dose is not usually sufficient and that the administration of repeated doses may be complicated or indeed rendered impossible by unexpected toxic effects. At best we can but realize that we have in some of the organic arsenical compounds and in some of the salts of bismuth and mercury powerful spirocheticidal medicaments, but that their administration must be guided by our present knowledge of their absorption and elimination and their pharmacological and toxicological effects in *sick* human subjects as well as in normal lower animals. Furthermore, we must possess a sound working knowledge of the pathology of syphilis and the modifying influence upon treatment that may be exerted by diseases with which an individual patient may be struggling in addition to syphilis.

By reason of these widespread influences the treatment of syphilis is becoming a specialty in medicine, but owing to its prevalence the disease is encountered in all fields of medicine and surgery and belongs to no one specialty. Indeed, the complete and detailed diagnosis of chronic syphilis may require a very wide training in dermatology, neurology, psychiatry, opthalmology, rhino-laryngology, surgery and internal medicine. It is unwise to treat a lesion; the ophthalmologist, for example, may plan treatment for an interstitial keratitis or an optic atrophy and entirely overlook lesions elsewhere. I believe that the treatment of syphilis may properly become a specialty in medicine by reason of the special training and experience required for the treatment of the disease as a whole and particularly of the central nervous system, but its diagnosis belongs to no one specialty and frequently requires the cooperation of physicians highly experienced in several specialties.

Constitution as a Factor in the Treatment of Syphilis.—In other words, the intelligent and effective treatment of syphilis requires a thorough working knowledge of the principles underlying the mechanism of infection and the pathogenesis of the disease together with a knowledge of the immunological changes that occur, as, likewise, the pathological alterations that may be produced in different tissues and organs and the clinical and laboratory means for their detection. Furthermore, it is apparent that the constitution of different individuals influences the course of the disease and the amount of treatment required for its eradication or arrest. As stated by Schindler[2] for example, a man still in the secondary stage of syphilis required ten times as much treatment to change his Wassermann reaction to negative as did his wife, infected by him and also in the secondary stage. If the husband's spirochetes were arsenic-fast, why did they not retain this resistance in the body of the wife? Schindler believes that it is not a difference in strains of spirochetes but rather a different ability on the part of the patient's constitution to react to the infection and treatment. As recently stated by Finger[3] the clinical picture of syphilis has changed during the past two centuries with the result that the cutaneous lesions are becoming milder but with an increase of syphilitic aortitis and involvements of the central nervous system. It is likely that a part of this change is influenced by constitution and the present day strenuous habits of living which tend to increase injuries of the cardiovascular and nervous systems producing areas of lowered resistance and favoring localization of spirochetes.

Importance of Fundamental Principles in the Treatment of Syphilis.—The treatment of syphilis demands, therefore, a sound working knowledge of the underlying principles of the mechanism of infection and pathology of the disease, the rôle of acquired immunity, as well as a knowledge of the comparative curative properties of various antisyphilitic remedies including their pharmacological and toxicological effects. Unfortunately, however, there is too great a tendency to treat syphilis by set rules which is always apt to be the case when specific remedies are available for the treatment of diseases; this may result in too little treatment for most cases, too much for some and meddlesome or harmful therapy for others.

Some physicians still adhere to the belief that syphilis may be aborted by cauterization or excision of the chancre. For several hundreds of years this practice has had its adherents and many successes have been claimed, but Fournier's remarkably clear analysis of the situation from the clinical standpoint, together with his large experience, shows quite clearly that success can hardly be expected if the sore is actually a syphilitic chancre. As he points out not a few of the alleged successes have been due to the cauterization or

excision of "simple chancres," that is, non-syphilitic abrasions, ulcers or herpetiform lesions, with an incubation period of only one to twelve days after exposure and infection. Since the discovery of *Spirochæta pallida*, Neisser, Brown and Pearce and others have shown, in experimental infections of monkeys and rabbits, that the organisms may reach the neighboring lymphatic glands within a few days after infection and many days or weeks before the development of the chancre. Undoubtedly syphilis may be prevented in some cases at least by the thorough application of soap and water, calomel ointment or some other spirocheticidal substance within an hour or two after exposure, but if one or two days have elapsed, abortion of the disease requires the administration of arsphenamin or an allied compound. As Fournier has stated, "*cauterization of a syphilitic chancre, even in its earliest stage, is absolutely powerless to prevent constitutional infection.*" The same is true of excision. Yet we quite commonly hear of physicians "cauterizing" penile sores and claiming thereby to abort syphilis; every once in a while we see cases of chronic syphilis who have relied upon this procedure alone and are dumbfounded to learn of its failure.

The rapid generalization of infection with *Spirochæta pallida* by the lymphatic and blood streams after the appearance of the chancre, is not sufficiently realized and within the last few years has lead to the more frequent examination of the spinal fluid for evidences of neural invasion even during the early stages of the disease. The old idea that infection of the central nervous system is only a late accident in syphilis should be abandoned and spinal puncture, with careful cytological, chemical and immunological examinations of the cerebrospinal fluid, resorted to within the first year after contraction of the disease, to determine whether or not these important tissues have been invaded and infected and treatment given accordingly.

In this connection the question of specific tissue strains of *Spirochæta pallida* has commanded a great deal of attention within the last few years and especially with reference to the existence of a specific strain for the brain and spinal cord, the so-called "neurotropic strain." The evidence for and against this hypothesis has been reviewed in Chapter XXXVI, but here it may be mentioned that no evidence at all is furnished by the size and appearance of the chancre or secondary lesions. It is commonly stated that the "neurotropic strain" produces a small erosive type of chancre with poorly developed secondary skin lesions, while the less dangerous "dermotropic strain" produces a large chancre and florid secondaries. But clinical experience does not substantiate this claim. It is true that in some families neurosyphilis develops so early and so frequently as to lend weight to the supposition that a specific neurotropic strain of *Spirocheta pallida* exists in the production of paresis and tabes, but such may be explained on the basis of inherited factors of predisposition and the results of experiments with rabbits upon this question of specific strains have been seriously questioned by the possibility of confusion with the organism of rabbit spirochetosis—*Spirochæta cuniculi.*

A common error in the treatment of chronic syphilis is to expect the total disappearance of all lesions along with a complete disappearance of all symptoms and functional defects. It is true that with treatment syphilitic exudates and fibrous tissues may become absorbed with at least partial restoration of function, but when a tissue has been completely destroyed as important nerve cells or tracts, restoration of function cannot be expected even if it were possible to prevent further destruction. Furthermore a mental picture of the pathological changes produced by chronic infection with *Spirochæta pallida* aids greatly in a proper understanding of the mechanism of medication and the necessity for administrating compounds in such

manner as will best favor gradual penetration of the inflammatory tissues in which the parasites are apt to be imbedded.

Furthermore, in connection with this subject of the influence of pathology upon treatment and prognosis, it should not be forgotten that the co-existence of some other non-syphilitic disease may require due consideration in our therapeutic efforts. For example, leprosy in a syphilitic is sometimes rendered worse by the administration of potassium iodid which favors renewed activity of the leprosy bacilli; the same is sometimes encountered in tuberculosis.

And few subjects in syphilis are as little understood as the immunological changes in this disease. To-day it is hardly necessary to raise the question as did Fournier in his treatise upon the treatment of syphilis, whether it is necessary to treat every case of syphilis. No better answer to this question can be found anywhere in literature than contained in the first two chapters of his book, only to-day we have the advantage of a deeper knowledge of the etiology and the results of immunological discoveries and investigations in experimental and human syphilis for substantiating his claim that all cases require treatment. That is to say, while a very exceptional case of syphilis may completely recover by the operation of his own cellular and humoral immunological agencies, this can never be depended upon; that there is "no criterion by which we can estimate the quality of early syphilis and its future progress" and that "in the case of syphilis the present is in no way the mirror of the future."

Immunity certainly does exert an important rôle in the fate of the syphilitic and particularly in the part it plays in protecting organs against progressive infection with *Spirochæta pallida;* likewise in the resistance offered superinfection and re-infection in syphilis. Few subjects in this disease are more interesting and likewise more important in relation to diagnosis, prognosis and even of specific and general treatment, but these subjects have been already discussed in Chapter XXXVII.

From the standpoint of serological changes in relation to diagnosis, treatment and prognosis of syphilis, mention need only be made of the complement-fixation reaction with serum and the colloidal gold reaction with spinal fluid. It is my conviction that the complement-fixation reaction in syphilis is without parallel in medicine as a valuable aid in diagnosis, when a few simple principles concerning its limitations are understood and properly evaluated. The test is not at all intricate for properly trained and experienced workers; certainly it offers chances for technical errors as is true of all laboratory tests, even the simplest, but technical errors can be easily reduced to a negligible minimum and biological errors may occur only in frambesia and trypanosomiasis. With a technically acceptable method the physician need not worry so much about the possibility of falsely positive reactions, but rather of falsely negative reactions. Altogether too frequently physicians depend upon the serum test for aiding the diagnosis of the chancre, when it should be realized that the reaction may be negative at this stage since sufficient time may not have elapsed for the production of the so-called "reagin" or complement-fixing antibody-like substance. The importance of early diagnosis and prompt treatment is still too frequently overlooked and in the majority of cases of primary syphilis the diagnosis may be made or greatly aided by the direct microscopical examination of the secretions of the chancre for *Spirochæta pallida* by appropriate staining methods or better, by means of a dark-field microscopic examination.

Furthermore, too much weight is ordinarily placed upon a single negative reaction in excluding the diagnosis of latent syphilis, when the pathology of syphilis should be remembered to the extent that *Spirochæta pallida* may be

so greatly reduced in virulence as to produce little or no tissue reaction and consequently too little "reagin" in the serum and spinal fluid for detection in the test-tube. The Bordet-Wassermann test is an invaluable aid in diagnosis and as a control on treatment, but only when it is properly understood and employed. Great harm is being constantly done by the blind use of the test—both by those who place too much confidence in it and by those who have no confidence in it at all.

Like so many subjects in medicine there is a valuable middle ground; if serologists will only realize their responsibility in conducting the test in a technically correct and acceptable manner and if clinicians will only take enough time for acquiring a sound working knowledge of its advantages and limitations and honestly admit that their clinical opinions and diagnoses are not infallible, the test is of incalculable value for aiding the diagnosis of syphilis after the primary stage and, under certain conditions, of value as a check in the treatment of the disease.

And in the actual treatment of syphilis let us properly differentiate between the treatment of early and chronic syphilis, because conditions are not the same in both. In the former the infection has not brought about the profound tissue changes which in the latter may influence our choice of drugs, their dose and manner of administration. We must have a proper understanding of the relative spirocheticidal properties of various medicaments, their absorption and elimination as well as their toxicological effects. We must resolutely refuse to adopt into our therapeutic armamentarium drugs exploited for commercial reasons only, until sufficient and appropriate laboratory studies have been made to warrant their use in the treatment of human syphilis possibly to the exclusion of compounds of proven therapeutic value. Let us realize that it is possible by animal experimentation to obtain a very accurate gauge of the spirocheticidal activity and toxicity of any compound proposed for the treatment of syphilis and let us refuse to use any compound unless such investigations have been made by responsible individuals. Of course some medicaments are useful in syphilis even though lacking in direct spirocheticidal activity; the iodids, for example, are not greatly spirocheticidal in the doses ordinarily administered, but nevertheless are of aid in the treatment of chronic syphilis. But let no one delude himself into believing that the iodids alone will cure syphilis; not infrequently we meet with cases of chronic syphilis to whom physicians have administered nothing but potassium iodid even in the early stages. Of course, the measure of the spirocheticidal activity of a medicament may not be an estimate of its sole therapeutic power; sodium cacodylate, for example, may favorably influence a syphilitic lesion but its curative power is so much less than arsphenamin, neoarsphenamin and allied compounds that it would appear to be a waste of time to administer it and especially since its curative properties in experimental syphilis are known to be almost negligible. Such things as intramuscular injections of milk or other forms of non-specific protein therapy may aid in the treatment of syphilis as they may in some chronic bacterial infections, but it is imperative for physicians to have a sound working knowledge of what each drug is known to do or capable of doing in the treatment of syphilis, before he is justified in employing it. In general terms, medicinal compounds known to exert the most marked degrees of spirocheticidal effects in experimental syphilis of the lower animals, likewise prove most spirocheticidal and effective in syphilis of human beings and should be preferred in the treatment of syphilis providing this is possible from the standpoint of administration by an acceptable route and freedom from both immediate and late toxicological effects.

Finally it cannot be too strongly emphasized that all compounds known to-day as possessing spirocheticidal activity and curative properties in syphilis are capable of exerting toxicological effects and doing actual harm. I believe it is far more important to understand what these effects may be, and how to detect them by clinical and laboratory means, than to attempt defining dosage according to set rules. It must never be forgotten that susceptibility to the toxic effects of the drugs employed in the treatment of syphilis varies considerably among individuals and is probably influenced by the pathological changes produced by syphilitic or non-syphilitic infection. A knowledge of these immediate and delayed or late untoward effects, including the possibility of stimulating or provoking syphilitic infection into renewed activity by well meant therapeutic measures, will aid in preventing our falling into the error of meddlesome therapy and to be content to leave well enough alone under certain circumstances. Altogether too frequently a diagnosis of syphilis is taken as a signal for rushing in with therapeutic measures that may do more harm than good even though our drugs are known to be spirocheticidal agents and are properly administered.

I believe, therefore, that in any treatise upon the treatment of syphilis that more space should be devoted to a frank discussion of these and other fundamental principles than an endeavor to lay down formal and short cut rules for treatment in this or that stage. The latter are useful as guides for the treatment of typical cases, but syphilis is a disease capable of involving so many different organs which may modify any course of treatment, the medicaments employed are so powerful and capable of doing much harm as well as much good, the disease requires such prolonged treatment and good judgment, that it is folly to attempt describing its adequate treatment in a brief way or formulating therapeutic rules and regulations for all cases.

In the preceding chapters I have, therefore, discussed more completely these fundamental principles in relation to the treatment of syphilis and will now take up the actual treatment of the disease in its early and late stages.

CHAPTER LXVII

COMPARATIVE ADVANTAGES AND DISADVANTAGES OF THE ORGANIC ARSENICALS, MERCURIALS, BISMUTH AND IODID COMPOUNDS IN THE TREATMENT OF SYPHILIS

So many new compounds have been placed before the medical profession during the past twelve years for the specific treatment of syphilis that a great deal of confusion regarding their comparative advantages and disadvantages exists in the minds of not a few physicians called upon to treat the disease. Numerous questions frequently arise of which the following are examples: (1) How do arsphenamin, neoarsphenamin, silver arsphenamin, sulphar-

sphenamin, etc., compare in curative activity? (2) Are the American made arsphenamins as efficient as the original German products? (3) Have the bismuth compounds been proven curative in syphilis? (4) How do bismuth and mercurial compounds compare in curative activity? (5) Are there special indications for the arsphenamins in some cases, for mercury and bismuth in others, etc.? (6) Can the arsphenamins alone or bismuth alone, etc., be depended upon for the treatment of syphilis? These and a host of similar questions are constantly being raised and unfortunately final answers cannot yet be given to some of them. The best one can do is to seek answers from two main sources, namely, (1) the results of experiments in the treatment of syphilis of the lower animals where the conditions are such, under proper and acceptable conditions, that comparisons can be made with a fair degree of scientific accuracy and (2) the results of clinical experience. The latter is, of course, the more important of the two, but unfortunately the present day remedies and methods of treating syphilis cannot be evaluated in definite and final terms; one or more decades must elapse for "time" to tell the final story, but it is possible to describe the results being observed and to use these as a basis for formulating opinions. In this chapter I shall endeavor to formulate answers to some of these questions on the basis primarily of my own experiments and experience, together with the published observations of others; obviously it is inadvisable in a treatise of this kind to attempt a review of all of the available literature even if this were possible. After all, statistical reviews are usually very inaccurate and only broad and general deductions and conclusions are justifiable because syphilis as a disease manifests itself in many different ways in different individuals with many modifying conditions and influences and it is so easy to dissipate the obvious lesions and relieve symptoms with the drawing of hasty conclusions that do not stand the test of time.

Specific Treatment of Syphilis.—In the first place, what constitutes the specific treatment of syphilis? As Fournier has stated the word "specific" is one of those which every one interprets in his own way. The only correct definition is one that ascribes specificity to those medicinal compounds which exert a direct and peculiar destructive effect upon the parasite of the disease. But these effects may not occur in some cases; the word "specificity," therefore, is not synonymous with curative "infallibility." We are too prone to regard a specific remedy or specific treatment as unfailing; the remedy may be a specific in the true sense of the term and yet fail to even arrest the progress of a syphilitic infection, as, for example, in some cases of paresis. The parasites may possess a peculiar increased resistance to the destructive effects of the drug or the drug may not be able to enter into contact with the parasites in sufficient concentration to destroy them; these and other factors which we do not understand at present may nullify the specific activities of a particular compound even when administered in a most thorough and acceptable manner. But unquestionably the arsphenamins are less likely to fail than mercury, although they may fail just as quinin may fail in the treatment of malaria and as opium may fail to relieve some pains.

Comparative Spirocheticidal Activity of Specifics in Acute Syphilis of Rabbits.—With these few remarks on specific medication in syphilis, I may now pass on to a more detailed discussion of the spirocheticidal activities of the remedies regarded as exerting specific effects. For the purpose of comparing them in these respects, experiments in the treatment of rabbit syphilis have proven of some value, because the final results can be obtained within a year whereas in human beings many years must elapse and, indeed, the final results are ascertainable in only a very small percentage of cases.

The curative activity of any drug in syphilis of the rabbit or human being is probably dependent not only upon its direct spirocheticidal activity when once in union with the parasites, but likewise upon penetrability of syphilitic exudates and the degree of stimulation of antibody production. The latter does not refer to the engendering of antibodies by the medicament itself; as stated in Chapter XXXVII, there is little or no evidence to support the hypothesis that such occurs in either the human being or lower animal, but medicaments probably vary in their power of releasing antigenic substances from spirochetes which in turn engender some antibody production. Probably antibody production under these circumstances bears a relation to spirocheticidal activity, but there is no evidence available upon which to base an opinion.

Under ordinary circumstances syphilis of the rabbit is much milder than syphilis of the human being although as stated in Chapter XXI, suppression of the primary lesion sometimes results in the widespread distribution of *Spirochæta pallida* with the production of lesions of the skin and mucous membranes, lymph-glands, bones, special organs, etc., similar to the lesions of syphilis in the human being. But natural immunity in the rabbit to *Spirochæta pallida* is more marked than in human beings; likewise, the immunity response in untreated and treated syphilis of this animal is more decided and these factors render the cure of syphilis of the rabbits much easier of accomplishment than syphilis of human beings. Nevertheless experiments in the chemotherapy of rabbit syphilis have yielded data of much value regarding the curative activities of various medicaments and the size, frequency, and route of their administration, just as valuable data of a similar nature have been obtained in the chemotherapy of experimental trypanosomiasis of this animal for application in the treatment of trypanosome diseases of human beings.

Comparison of the Curative Activity of Various Medicaments in Acute Primary Testicular Syphilis of Rabbits.—In Chapters XXIII to XXIX I have described in detail the curative properties of a large number of different compounds in experimental syphilis of the rabbit; not all are suitable or worthy for use in the treatment of human syphilis. In the following table the better known and more useful of these are listed along with the maximum tolerated and minimum curative doses of each as determined in my laboratory for purposes of comparison. As previously stated in Chapter XLIV, the maximum tolerated dose of any medicament for the rabbit has only a broad and general relation to its toxicity for the human being. In the latter, we may have hypersensitiveness and minor reactions develop after the administration of much smaller doses according to body weight, but in a general manner compounds best tolerated by the rabbit are probably best tolerated by human beings. The minimal curative doses listed in table 6 are average amounts capable not only of dissipating the local testicular or scrotal lesions but effecting complete sterilization of the lymphatic glands and thereby permanent cures:

TABLE 6.—COMPARISON OF THE CURATIVE PROPERTIES OF SINGLE DOSES OF VARIOUS MEDICAMENTS IN TESTICULAR SYPHILIS OF THE RABBIT

COMPOUNDS	MAXIMUM TOLERATED DOSE PER KILO (GMS.)	MINIMAL CURATIVE DOSE PER KILO (GMS.)	CHEMOTHERAPEUTIC INDICES
Neoarsphenamin	0.350	0.020	1:18
Sulpharsphenamin	0.300	0.022	1:14
Silver arsphenamin	0.110	0.010	1:11
Arsphenamin	0.120	0.012	1:10
Sodium arsphenamin	0.210	0.020	1:10
Galyl	0.100	0.020	1:5
Tryparsamid	0.900	0.400	1:2
Sodium and potassium tartro-bismuthate	0.200	0.050	1:4
Mercuric chlorid	0.003	0.003	1:1
Salicylate mercury	0.005	0.005	1:1
Flumerin	0.030	0.030	1:1
Potassium iodid	0.310	0.300	0

The chemotherapeutic indices show in a general manner the comparative spirocheticidal activities of these various compounds employed in the treatment of syphilis. Unquestionably arsphenamin and its substitutes stand at the head of the list followed in order by the pentavalent arsenicals, bismuth, mercury and the iodids. If the *chemotherapeutic indices* may be used for expressing comparative spirocheticidal effects, these various compounds may be listed as follows:

Arsphenamin, neoarsphenamin, sulpharsphenamin and other trivalent organic arsenicals	10 to 18
Tryparsamid and other pentavalent organic arsenicals	2 to 6
Bismuth	4 to 5
Mercury	1
Iodids	0 to 1

These figures are based upon single doses for rabbits, sufficient for complete sterilization including the lymph-glands and not merely for the dissipation of local testicular or scrotal lesions alone; the amounts required to merely cause the disappearance of spirochetes and healing of the local lesions are much smaller.

Comparative Spirocheticidal Activity of Specifics in Human Syphilis. This naturally brings one to the consideration of a more important practical question, namely, the comparative specific spirocheticidal activity of the large number of arsenical, mercurial, bismuth and iodic compounds employed in the treatment of human syphilis. Here our difficulties are infinitely greater than in syphilis of the lower animals because it is almost impossible to compare one remedy with another under strictly acceptable conditions because of variations in the virulence and duration of infection, the influence of occupation, general health, immunological response, sex, etc. In rabbits we may work with a single strain of *Sp. pallida*, use animals of the same breed and stock, approximately of the same weight and general health, and infect a large series at the same time, choosing for our tests, animals presenting similar lesions and treating each strictly according to body weight. We may keep them under constant observation and make examinations for spirochetes as frequently as we choose, at stated intervals and finally judge the results by necropsies and the inoculation of fresh animals with emulsions of the lymph-glands and other organs of the treated animals for surviving spirochetes. It is not possible however, to duplicate these conditions in human beings. We may estimate the time required for the removal of spirochetes from chancres and mucous patches and for the dissipation of these and other obvious lesions but we cannot ordinarily give our drugs strictly according to body weight and we cannot secure enough cases showing similar lesions of approximately the same duration and extent, etc., as are so easily obtained in rabbit syphilis. Therefore, we must resort to animal experimentation for data of real value although this data is applicable and referable only to acute syphilis. In chronic syphilis the location of the spirochetes, the degree of tissue reaction about them, etc., are factors greatly modifying our conception of the comparative values of specific spirocheticidal remedies. But here again rabbit syphilis yields information of value since it is possible to produce chronic lesions by infecting and castrating large numbers and selecting animals presenting approximately the same lesions for our tests.

But if we adhere closely to our theme we may express in comparative terms the specific spirocheticidal activities of the various remedies employed in the treatment of human syphilis. These, however, are only a small part of the practical value of the respective compounds; one must keep in mind their pharmacological and toxicological effects, their penetrability of syphilitic exudates, etc., for properly expressing a complete estimate of their value in syphilis. But leaving out for the present these important modifying factors, I believe that the comparative spirocheticidal properties of various remedies used at present in the treatment of syphilis of human beings may be arranged in the following order:

Group I. Arsphenamin and silver arsphenamin highest and about equal.

Group II. Neoarsphenamin, sulpharsphenamin, sodium arsphenamin and silver neoarsphenamin next and about equal; spirocheticidal activities

about two-thirds that of Group I but varying considerably, and especially in the case of neoarsphenamin, according to the brand employed.

Group III. The bismuth compounds next; spirocheticidal activity about one-fifth that of Group I but varying considerably according to the compound employed.

Group IV. Tryparsamid, sodium oxyaminophenyl arsenate ("189"), amino-arsenophenol (Pomaret's "132"), "galyl" and other pentavalent arsenicals next; spirocheticidal activity about one-sixth that of Group I.

Group V. The mercurial compounds varying greatly in therapeutic activity according to content of mercury, rapidity of dissociation and ionization of mercury, solubility, etc.

This classification is based partly upon the results of experiments in the treatment of rabbit syphilis and more especially in the treatment of acute syphilis of human beings as observed personally or gathered from the literature. In a broad and general manner, I believe it answers the question concerning the comparative specific spirocheticidal activities of the respective medicaments. It does not, however, necessarily indicate the order of choice in the treatment of syphilis; tryparsamid for example, is very much less spirocheticidal than arsphenamin, but is said to be more efficacious in the treatment of paresis, partly on the basis of claims that it better penetrates the tissues of the central nervous system. It is necessary, therefore, to discuss the respective compounds more broadly before arriving at an estimate of their practical value; in other words, one compound may be better than another for a certain clinical type of syphilis even though it is less spirocheticidal in acute syphilitic lesions of rabbits or human beings.

Advantages and Disadvantages of Arsphenamin in the Treatment of Syphilis.—What is the present status of arsphenamin or salvarsan in the treatment of syphilis? Fifteen years have now elapsed since it was discovered and introduced for the treatment of syphilis by Ehrlich, Hata and Bertheim and an enormous literature has accumulated upon its use in the treatment of this and other protozoan diseases. As stated above it is still too early to express a final opinion of its value in the cure of syphilis because only time can tell the final story in terms of the incidence of late tertiary syphilis of the cardiovascular and central nervous systems of individuals treated in the early stages and regarded as "cured" according to our present day criteria. But I believe the results of laboratory and clinical studies warrant the following statements at the present time:

1. Arsphenamin or salvarsan is the best spirocheticide in the body known to-day. As will be shortly discussed, silver arsphenamin is somewhat more spirocheticidal in rabbit syphilis but in the treatment of human syphilis the slight differences are not usually apparent in the majority of cases. Within the last six or seven years neoarsphenamin has gradually superceded arsphenamin in the treatment of syphilis, because of its lower toxicity and greater ease of administration, but the fact remains that it is usually inferior in spirocheticidal activity. It is commonly stated that 0.9 gm. of neoarsphenamin is equal in curative activity to 0.6 gm. of arsphenamin; this is true insofar as arsenic content is concerned, but in my experience slightly more than this amount of neoarsphenamin is required to equal arsphenamin which I believe is largely because neoarsphenamin is eliminated more rapidly than arsphenamin. I see no escape from the conclusion that, judged solely on the basis of spirocheticidal activity and specific medication, arsphenamin is the sovereign remedy for syphilis to-day.

2. Arsphenamin is the most stable of the organic trivalent arsenicals. As will be shortly discussed, neoarsphenamin, sulpharsphenamin and sodium

arsphenamin may vary considerably in spirocheticidal activities as prepared in different laboratories and even in the same laboratory, but arsphenamin remains remarkably constant; and this is a point of considerable importance in favor of arsphenamin, because when the physician employs it in the treatment of syphilis, one can be sure of spirocheticidal effects whereas with the neoarsphenamins this is not always the case. From the standpoint of spirocheticidal activity the arsphenamins prepared in this country have been practically identical with the original German salvarsan. One sometimes hears it stated that the clinical results observed with the original German salvarsan between 1912 to 1916 were superior to those observed since 1916 with American, English and French products; I am not able to discuss the question from the standpoint of the English and French arsphenamins because of a lack of experience with them, but as far as I am able to judge clinically and more especially by laboratory studies, American made arsphenamins are equal on an average basis to the original German arsphenamin manufactured in the years from 1912 to 1916. It is very easy to be mislead by first impressions and the word "original" has a strong appeal to many minds as applied to the German arsphenamin or salvarsan prepared by Ehrlich's method, but I can only repeat that it is my experience that the original salvarsan was not superior in spirocheticidal activity to present day American made arsphenamin. It is true that some lots have proven more trypanocidal and spirocheticidal than others, but we cannot make our tests mathematically correct and the *average* parasiticidal effects of American arsphenamin equals the *average* effects of German salvarsan.

3. Arsphenamin is more slowly eliminated than neoarsphenamin and sulpharsphenamin. This is probably because it is precipitated at the hydroxyl ion concentration of the blood with the result that it is fixed by the tissues and is eliminated more slowly, but for these reasons it would appear better adapted for the treatmet of chronic syphilis than neoarsphenamin and sulpharsphenamin. This is especially true of the treatment of neurosyphilis since it appears that arsphenamin penetrates the tissues of the brain and cord better than neoarsphenamin. On the other hand, cases of chronic syphilis are more likely to develop toxic accidents because of focal infections and various pathological changes in the organs of elimination and, it is possible, that arsphenamin is more dangerous than neoarsphenamin in the vascular types of neurosyphilis because of its greater vasculo-toxicity.

4. Arsphenamin is undoubtedly more toxic than neoarsphenamin and sulpharsphenamin. It is much more likely to produce immediate and early toxic reactions because of colloidal reactions in the blood as well as by its greater vasculo-toxicity. I believe it is more likely to produce dermatitis and allied accidents than neoarsphenamin but less so than sulpharsphenamin; it is also more likely to produce jaundice because more hepatoxic and longer retained in the liver than neoarsphenamin. It is also more likely to produce neural and cardiovascular Herxheimer reactions because of its greater vasculo-toxicity and spirocheticidal properties.

5. Arsphenamin is more difficult to administer than neoarsphenamin and sulpharsphenamin. Many fatalities have been caused by failure to neutralize or alkalinize the solutions. It tends to produce greater irritation of the veins. It is much more difficult to give a series of injections than is the case with neoarsphenamin and sulpharsphenamin. Because of these technical difficulties and toxic effects, patients are less likely to take an adequate number of injections and not a few physicians are likely to undertreat their cases. Undoubtedly neoarsphenamin and sulpharsphenamin have induced a larger number of physicians to undertake the treatment of syphilis and have

encouraged the more thorough treatment of the disease by both physician and patient.

To sum up, it may be stated that arsphenamin is the best spirocheticide known to-day for the specific treatment of syphilis; it is the arsenical of choice in the treatment of both acute and chronic syphilis under these conditions: (*a*) when the patient is in good general condition from the standpoint of risk from toxic reactions; (*b*) when the patient is able to rest for at least twelve to twenty-four hours after injection to recover from minor reactions; (*c*) when the physician possesses experience and skill in its administration; also the time to devote to close attention to details and especially proper alkalinization of solutions and the slow injection of dilute solutions. It is not the arsenical of choice for the treatment of ambulatory patients who must attend to their daily work and duties without interruption; or for those who must be treated secretely and who therefore fear being incapacitated by toxic reactions; or for the busy physician who cannot spare the longer time required for its administration; or for individuals with difficult veins since injection by gravity is more difficult than the injection of concentrated solutions of neoarsphenamin or sulpharsphenamin by syringe methods; or for those patients who cannot afford the greater expense of an adequate course of arsphenamin injections since the physician must usually expect a larger fee because of the greater time and skill required for their administration.

But I believe that we have allowed the ease of administration of neoarsphenamin and sulpharsphenamin to overshadow the advantages of arsphenamin and I predict that we will come back again to the employment of arsphenamin more frequently than at this writing, when it is discovered, as I believe it will be, that the incidence of late tertiary lesions is greater after treatment with neoarsphenamin and sulpharsphenamin than after adequate courses of arsphenamin.

Advantages and Disadvantages of Silver Arsphenamin in the Treatment of Syphilis.—My experience with silver arsphenamin has been much less than with arsphenamin and has been confined entirely to American made products. I believe it is slightly more spirocheticidal than arsphenamin and it is said to be more efficacious than the latter in the treatment of neurosyphilis because of higher penetrability of the tissues of the central nervous system. Otherwise, in my opinion, it is not superior to arsphenamin in the treatment of either early or late syphilis. It is just as likely to produce toxic reactions and probably has the added danger of producing argyria when administered as frequently and in the dosage required for the adequate treatment of both early and chronic syphilis. It is easier to administer, however, than arsphenamin because the solutions do not require alkalinization. Small doses as 0.1 gm. dissolved in 20 c.c. of sterile water may be given by syringe injection, but the usual dose of 0.4 gm. requires gravity injection of dilute solutions. It is slightly more toxic for the lower animals than some brands of arsphenamin and in my experience, doses of 0.4 gm. are just as likely to produce toxic reactions in adult cases of syphilis as 0.4 gm. doses of arsphenamin. In my limited experience I have found it to have in general the same advantages and disadvantages of arsphenamin; I know of no special reasons for preferring it to the latter unless it be in the treatment of neurosyphilis, which opinion is based more upon a review of the literature than my personal experience with it in the treatment of these cases. Within recent years the use of silver arsphenamin has decreased; Michelson[1] has reviewed the literature up to 1921.

Advantages and Disadvantages of Neoarsphenamin in the Treatment of Syphilis.—Neoarsphenamin is undoubtedly the most widely used arsenical

employed to-day in the treatment of syphilis. The greater ease of administration, greater safety and greater freedom from untoward effects have quickly won for the compound greater favor with the majority of physicians than arsphenamin and other arsenical compounds. It was particularly popular during the World War in the armies of the United States, France and England, because of the ease of its administration and hundreds of physicians returning to civil practice have continued to use it in the treatment of syphilis. Its rapid solubility, ease of preparing solutions, the fact that concentrated solutions may be injected and low toxicity constitute its greatest advantages. For the lower animals it is at least two to four times less toxic than arsphenamin in alkaline solution and it is less likely to produce toxic reactions in human beings. These properties have encouraged the wide use of neoarsphenamin, have done more than any other single factor to foster the more thorough treatment of syphilis and has placed the modern treatment of the disease with the organic arsenicals within the reach of the majority of physicians instead of in the hands of relatively few specialists.

But neoarsphenamin is only about half as spirocheticidal as arsphenamin; in my experience, 0.9 gm. per 60 kilograms does not always or uniformly possess the same spirocheticidal activity as 0.6 gm. of disodium arsphenamin per 60 kilograms. As stated in Chapter XII, neoarsphenamin is much more likely to vary in trypanocidal and spirocheticidal activities than arsphenamin; this is not only true of neoarsphenamin prepared in different laboratories but to some extent with different batches prepared in the same laboratory. To-day there exists a remarkable variation in the parasiticidal effects of different brands of neoarsphenamin employed in the treatment of syphilis. I have repeatedly found samples on the market unable to cure syphilis of rabbits in doses as high as 0.045 gm. per kilogram whereas the average single curative dose should be 0.020 gm. per kilogram of weight for these animals. It is true that repeated doses may dissipate the obvious lesions of syphilis in human subjects and relieve some of the symptoms, but I doubt that the effects will be permanent and I believe that a high incidence of tertiary syphilis will be observed in the next ten to twenty years among syphilitics who believed themselves cured by series of injections of some brands of neoarsphenamin being employed to-day in the treatment of acute syphilis. Manufacturers of neoarsphenamin are laying entirely too much stress upon the flash solubility and low toxicity of their products; more attention should be given to their curative activity. In the competitive race for compounds of low toxicity, spirocheticidal activity has been overlooked and, I believe, that with some brands at least, technical procedures resulting in the lowering of toxicity for the rat have at the same time lowered toxicity for the spirochete of syphilis. I regard this situation as a serious one because I believe physicians and patients are not infrequently being deluded and I hope that the Hygienic Laboratory of the Public Health Service will establish a standard of parasiticidal activity for neoarsphenamin just as it has long since done for toxicity, with wonderful and praiseworthy results. Few realize better than I do what this entails in the way of work, expense and responsibility; indeed, tests with rabbit syphilis are out of the question on a broad scale because of the large number of animals required and since at least four months are required to obtain final results, but, as shown in Chapter X, trypanicidal tests are readily, rapidly and cheaply conducted and I am convinced that the trypanocidal activity of neoarsphenamin is a good and acceptable index of its spirocheticidal properties. I believe that manufacturers should be required to determine the trypanocidal activity of at least one out of every three to five batches of neoarsphenamin produced and that the Hygienic Laboratory

should check up the results at frequent intervals. I hope that physicians in general will take a greater interest in this subject and show the manufacturers that they are interested just as much in the question of curative activity as the physical qualities of the drug and its low toxicity.

As stated above, the trypanocidal and spirocheticidal properties of neoarsphenamin are apt to vary even among different lots dispensed by the same laboratory; for this reason I never treat a patient with the same lot number, but if 12 to 15 injections are to be given as a course, I endeavor to make up the series with at least two or three different lots of the compound. I believe this is a practical way for overcoming in part at least, the regrettable error of treating with a single batch of the drug below the average in curative activity.

Furthermore, as described in Chapter XII, neoarsphenamin is likely to deteriorate in the ampules and these changes affect not only the physical properties and toxicity but also to some extent the parasiticidal properties. Naturally if the product has oxidized slightly one would expect an increase of toxicity and an increase of parasiticidal activity, but I have found some lots of orange or brown color with reduced trypanocidal activity due, presumably, to far advanced oxidation. It is advisable not to use neoarsphenamin more than a year old even though it appears acceptable from the standpoint of physical properties; pharmacists sometimes overstock and dispense to physicians neoarsphenamin several years old and this practice is to be condemned and carefully avoided.

Neoarsphenamin, therefore, possesses the great practical advantages of ease of administration and safety; it is the remedy of choice to-day for the office treatment of ambulatory patients requiring arsenical therapy who cannot afford to be incapacitated by even minor reactions. The ease of administration also greatly reduces the expense; at least it should do so, and thereby enable patients of average or reduced financial status to undergo more thorough treatment than in the pre-neoarsphenamin days. But it must always be remembered that the drug is only about one-half as curative as arsphenamin at best, that if poor products are used treatment will be insufficient with the danger of producing arsenic fastness of surviving spirochetes and that more injections and larger doses are thereby required; also that the compound varies in curative activity and is more likely to deteriorate and therefore requires more vigilance on the part of the physician. It is possible to secure neoarsphenamin in which the dose of 0.9 gm. is practically equivalent in curative activity to 0.6 gm. of arsphenamin and with such I believe that neoarsphenamin is the best and most satisfactory arsenical available to-day for the routine treatment of syphilis even though arsphenamin, silver arsphenamin or sulpharsphenamin may be indicated in special cases.

Advantages and Disadvantages of Neosilver-arsphenamin in the Treatment of Syphilis.—Neosilver-salvarsan has been used in Germany during the past three years and a number of reports have been rendered by Weber and Hillenberg,[2] Dub,[3] Weber and Hillenberg,[4] Duhot,[5] Krebs,[6] Ziegler,[7] Steuhmer,[8] Bruhns and Bluemener,[9] Liebner and Rado,[10] Dreyfus,[11] Galewasky,[12] and others, showing in a general manner that it is somewhat superior to neoarsphenamin in that the solutions do not oxidize as rapidly and are more stable, that toxic reactions are less frequent and that spirocheticidal effects are somewhat greater. To the best of my knowledge the compound has not been employed in America and I have had no experience with it at all either clinically or in rabbit syphilis. The data and arguments in favor of adopting it in preference to neoarsphenamin and sulpharsphenamin, however,

would have to be quite conclusive to convince me to employ the compound, because I believe extravagant claims have been made for silver arsphenamin and I greatly dislike giving a series of intravenous injections of silver even though the danger of producing argyria may be more theoretical than established fact.

Advantages and Disadvantages of Sulfarsenol or Sulpharsphenamin in the Treatment of Syphilis.—*Sulfarsenol*, a French arsenical composed of arsenobenzol with formol and sodium acid sulphite, but the method of preparation of which is kept a trade secret, has been employed mostly in Europe in the treatment of syphilis since 1920; *sulpharsphenamin*, a sulphurous acid ester of arsphenamin made from arsphenamin, formaldehyd, and sodium bisulphite, was prepared by Voegtlin, Johnson and Dyer[13] in 1922, and is believed to be closely similar to sulfarsenol in preparation and identical in properties; it is being widely employed at present in America.

The latter preparation is quite similar to neoarsphenamin, differing by the presence of one additional atom of oxygen; it contains from 22 to 24 per cent. of arsenic, is easier to manufacture and possesses greater stability in both dry form and in water solution. Both sulfarsenol and sulpharsphenamin possess the same ease of administration as neoarsphenamin, since they are quickly soluble, do not require alkalinization and may be administered in concentrated solutions.

In my experience, sulpharsphenamin is slightly less spirocheticidal in rabbit syphilis than the best brands of neoarsphenamin when both are given by intravenous or both by intramuscular injection in the same doses per body weight; I have had much less experience with sulfarsenol, but the lots which I have tested have been uniformly less trypanocidal and spirocheticidal than sulpharsphenamin and I have no hesitation whatsoever in expressing a preference for the latter even though they are supposed to be practically identical in chemical composition.

As stated in Chapter XXIX, arsphenamin, neoarsphenamin and sulpharsphenamin are distinctly more trypanocidal and spirocheticidal in experimental infections by intramuscular than by intravenous injection, but the first two produce so much local reaction in doses of 0.2 gm. or more that they cannot be given by subcutaneous or intravenous injection whereas sulpharsphenamin may be administered by this route if not more than 0.6 gm. is deposited in any one area. Herein lies the chief advantage of sulpharsphenamin. When administered to syphilitic rabbits and to human beings with chancres and secondaries by *intravenous injection*, sulpharsphenamin, in my experience, has been slightly less curative than the best brands of neoarsphenamin and only about one-half as curative as arsphenamin; but sulpharsphenamin in dose of 0.6 gm. by *intramuscular or subcutaneous injection* is usually more spirocheticidal than 0.6 gm. of neoarsphenamin by intravenous injection and almost equal to arsphenamin by intravenous injection, although the average results have shown that the latter is slightly but distinctly more spirocheticidal.

In other words, there is no use in my opinion comparing sulpharsphenamin with neoarsphenamin by intravenous injection; I am convinced that the best brands of the latter are superior to the best brands of the former in curative activity by this route of administration, although the difference is slight and much better elicited by careful animal experiments than by clinical studies and observations. Likewise, there is no use in comparing sulpharsphenamin with neoarsphenamin by intramuscular injection, insofar as curative activity is concerned; on the basis of trypanocidal tests with rats and spirocheticidal tests with rabbit syphilis, the latter is more active. But

neoarsphenamin cannot be given adult cases of syphilis by intramuscular or subcutaneous injection in sufficiently large doses, whereas sulpharsphenamin may be given by these routes and undoubtedly 0.4 gm. of sulpharsphenamin by intramuscular injection is much more spirocheticidal than 0.4 gm. of neoarsphenamin in intravenous injection. But how does a dose of 0.4 gm. of sulpharsphenamin per 60 kilograms of weight by intramuscular injection compare in parasiticidal activity with 0.9 gm. of neoarsphenamin per 60 kilograms by intravenous injection? In my experience, the brand of neoarsphenamin which I have used has proved equal to or slightly better than the two brands of sulpharsphenamin employed and decidedly better than the one brand of sulfarsenol. I am convinced that sulpharsphenamin and sulfarsenol by intravenous injection are inferior in spirocheticidal activity to the brand of neoarsphenamin which I have used and that the latter is to be preferred when intravenous injections are to be given in the treatment of *acute early* syphilis. But in the treatment of *chronic* syphilis and especially of neurosyphilis, it would appear that intramuscular injections of sulpharsphenamin are superior to intravenous injections of neoarsphenamin; I base this statement almost entirely upon the work of Voegtlin, Smith, Dyer and Thompson,[14] showing that it has superior penetrative properties for the brains and spinal fluids of rabbits and more particularly upon the recent clinical report of Stokes and Behn,[15] rather than upon my own limited clinical experience. The latter report is the best so far appearing in the American literature, although numerous reports on sulfarsenol have appeared especially in France by Levy-Bing, Lehnhoff-Wyld and Gerbay,[16] Bernard,[17] Yernaux and Bernard,[18] Emery and Morin,[19] Hewins and Acre,[20] Doble,[21] Irgang,[22] Asch,[23] Boone and Weech,[24] Crawford and Fleming,[25] Durveux,[26] Papegaay and Rinsema,[27] Belding,[28] and others. It is not profitable for me here to review these reports in detail; some are favorable and some are unfavorable, but the general tenor has been to emphasize the fact that sulfarsenol or sulpharsphenamin may be given by either subcutaneous or intramuscular injection, that by these routes it has at least the curative activity of neoarsphenamin by intravenous injection and that toxic reactions with the exception of dermatitis, are fewer and less serious. Stokes and Behn, injecting 0.4 gm. in 1.2 to 1.5 c.c. of distilled water at 3 to 5 day intervals, have found one brand of sulpharsphenamin superior to neoarsphenamin in acute early as well as chronic, cardiovascular, neural and Wassermann-fast cases and they state that the drug by this route of administration has proved to be quite as effective therapeutically as arsphenamin and neoarsphenamin from the standpoint of spirillicidal action and of the effect on the blood Wassermann and spinal fluid reactions, on the healing of lesions, and on the general well-being of the patient. They believe they saw distinct superiority, in the treatment of neurosyphilis over the older drugs, and distinct evidence of superiority over neoarsphenamin intravenously in all aspects of syphilis. They have likewise given the most favorable report on the degree of local reactions of pain and tenderness in the muscles; they divided the dose 0.4 gm. between the two buttocks and gave the injections epifascially (intermuscularly) instead of intramuscularly. Most likely these technical factors account for the fact that, in 83 per cent. of their 1,360 injections, there was no local discomfort whatsoever. I thoroughly agree with them that it is well not to inject more than 0.2 to 0.4 gm. in one area; a few of my patients have complained bitterly and a few have absolutely refused injections of 0.4 to 0.6 gm. dissolved in 2 to 4 c.c. of sterile water in one area, although the sulpharsphenamin being dispensed at the present time as much less painful than formerly.

Belding has called particular attention to the high incidence (about 16 per cent.) of skin reactions following injections of sulpharsphenamin. I have observed the same in about 5 per cent. of injections and believe that intravenous injections are more likely to produce dermal accidents than intramuscular injections. It is noteworthy that Stokes and Behn observed only 3 per cent. of toxic reactions, two patients developing exfoliative dermatitis. If I understand their report correctly, the incidence of dermatitis was 1 to about 700 injections as compared with 1 to 4,300 injections of arsphenamin. This incidence is certainly much lower than my own, although I have included such mild reactions as localized urticaria and erythema, the development of which always induces me to stop the administration at once in order to avoid the possibility of producing the dreaded severe forms of dermatitis. It is interesting to note that Stokes and Behn gave injections of sulpharsphenamin without mishap to five individuals who had developed cutaneous reactions from arsphenamin and neoarsphenamin.

To sum up, the chief advantages of sulpharsphenamin are ease of administration, that subcutaneous or intramuscular injections may be given and that, by the latter route, the compound possesses the same or better specific spirocheticidal effects than neoarsphenamin by intravenous injection. For my own part, I still prefer intravenous injections of the neoarsphenamin I have been using for years for the treatment of acute early syphilis; for the treatment of chronic syphilis of adults and especially neurosyphilis and congenital syphilis of children however, I believe that sulpharsphenamin by intramuscular injection is worthy of trial and as manufactured at present skin reactions are much less frequent than observed one or two years ago when this product was first placed upon the market. As stated by Boone and Welch[28a] sulpharsphenamin by intramuscular injection is particularly well adapted for the treatment of congenital syphilis and Fergusson[28b] and others have found it well adapted for the treatment of syphilis afloat on war vessels. More recently Fordyce, Rosen and Myers[28c] have reviewed the literature on sulpharsphenamin along with their own laboratory and clinical investigations and state that the compound must be used with caution from the standpoint of reactions and purpura, that it is two and one-half times less active than neoarsphenamin therapeutically, that it has not shown any special affinity for the central nervous system and that clinically, no superior results were noticeable.

Advantages and Disadvantages of Sodium Arsphenamin, Sulphoxylate Arsphenamin and Galyl in the Treatment of Syphilis.—Sodium arsphenamin was produced in Germany in the early part of 1915, and has enjoyed a brief popularity as a substitute for arsphenamin, inasmuch as the solutions in water do not require alkalinization and concentrated solutions may be injected in exactly the same manner as neoarsphenamin.

In America, the drug has been used to some extent but has been gradually superseded by neoarsphenamin. The literature up to 1921 is mostly in German and has been well reviewed by Michelson and Siperstein,[29] so that I shall omit here the references. As stated in Chapter XII, I have found this compound slightly less trypanocidal than neoarsphenamin although its spirocheticidal effects in rabbit syphilis were about equal to neoarsphenamin insofar as could be judged in a few experiments. From the standpoint of ease of administration, toxicity and curative activity it is about on par with neoarsphenamin, although it is more toxic for rats and rabbits and, therefore, possesses a lower chemotherapeutic index than neoarsphenamin; it is certainly less curative than arsphenamin and produces about as much local reaction as neoarsphenamin so that it cannot be given intramuscularly. On the

whole, I believe the compound is slightly less efficient than the best brands of neoarsphenamin and, as stated above, it would appear that the latter is preferred by most physicians in the treatment of syphilis.

Sulphoxylate arsphenamin is a different preparation of secret manufacture. It is marketed as a fluid but has not been extensively used in Germany and not at all in America. Kumer[30] thought it had as much spirocheticidal activity in the treatment of rabbit syphilis as neoarsphenamin, but these observations were not confirmed in human cases of syphilis. To the best of my knowledge the compound is no longer employed for the treatment of syphilis.

Galyl or tetraoxydiphosaminodiarsenobenzene is also a secret preparation first prepared by Mouneyrat of Paris and named after Galan, who first noted the properties of arsenic. According to an analysis by the A. M. A. Chemical Laboratory,[31] the new "galyl" decomposes in water into sodium phosphate and sodium arsphenamin or else contains sodium arsphenamin and sodium phosphate, its injection apparently amounting to the administration of a mixture of phospharsphenamin (if any is present), sodium arsphenamin, sodium phosphate, sodium sulphite and sugar. During the World War the preparation was apparently widely used in Europe, since it was dispensed with sufficient sodium carbonate to enable one to dissolve it in water and administer by intravenous injection with the same ease as sodium arsphenamin or neoarsphenamin. However, but few reports on its use in syphilis have appeared among which may be mentioned those of Beurmann, Mouneyrat and Tanon[32] and Troisfontaines[33] in France; Foerster,[34] Spense[35] and Dudley[36] in England, and Bruner[37] and Thompson[38] in America.

In my laboratory, experiments have shown the compound about as toxic as arsphenamin for rabbits and rats with the trypanocidal and spirocheticidal activity of sodium arsphenamin; its chemotherapeutic index, therefore, is low. I have had no clinical experience with the compound but from laboratory experience and a review of the literature I regard it inferior to sodium arsphenamin and much inferior to the best brands of neoarsphenamin.

Advantages and Disadvantages of Pentavalent Arsenical Compounds as Sodium Cacodylate, Tryparsamid, Etc., in the Treatment of Syphilis.—The first organic compounds of arsenic to be used in the treatment of syphilis were such pentavalent compounds as *atoxyl* and *arsenophenolglycin*. Insofar as the treatment of syphilis is concerned, they are now only of historical interest since the doses required for specific spirocheticidal effects are too toxic, sometimes producing amblyopia in the case of atoxyl and skin reactions in the case of arsenophenylglycin. *Sodium cacodylate* also enjoyed a brief popularity for a time on the basis of causing the disappearance of chancres and secondaries, which is an example of how easy it is to foster new compounds upon the medical profession because of the comparative ease with which these lesions may be dissipated, as shown by the report of Marechal[39] on the use of two methylarsinates, sodium cacodylate and "arrhenal;" but since the unfavorable reports of Cole,[40] Nichols[41] and others with "mon arsone" these compounds have been discarded in the treatment of syphilis.

Pomaret and other French investigators, however, continue to enlist interest in the pentavalent arsenicals and especialy in the sodium salt of aminophenylarsenic acid ("eparseno" or "132"), a derivative of Ehrlich's "592," the sodium salt of oxyamino-phenylarsenic acid ("189") and other compounds of the same general class. Pomaret and Bloch,[42] Lepinay[43] Sherwood-Dunn[44] and others, for example, have warmly endorsed sodium aminophenol in doses of 0.12 to 0.36 gm. by intramuscular injection and state that the local pain is not greater than produced by mercury while the curative effects are equal to neoarsphenamin. They claim that the toxic effects are largely due to impurities removable by closer attention to technical details in manufacture; Fournier, Guénot and Schwartz[45] and others have made similar claims for the sodium salt of oxyaminophenylarsenic acid and Levaditi, Navarro-Martin, Fournier, Guénot and Schwartz[46] and Laurent[47] for the sodium salt of acetyloxyaminophenylarsenic acid ("stovarsol," "acetylarsan" or "190") by oral administration. I have given in previous

chapters the results of trypanocidal, spirocheticidal and toxicity studies in the lower animals; I have had no clinical experience with the compounds, but feel convinced that they are inferior to sulpharsphenamin in the treatment of syphilis by intramuscular injection, are more toxic and have no superior claims warranting their choice for the treatment of syphilis although they and the pentavalent compounds of arsenic in general, may be more useful in the treatment of trypanosomiasis. The only pentavalent arsenical compounds worthy of special consideration are *tryparsamid* and *stovarsol*, the former by intravenous injection in the treatment of neurosyphilis according to the reports of Lorenz, Loevenhart, Bleckwenn and Hodges,[48] Moore, Robinson and Keidel[49], Lorenz, Loevenhart, Reitz and Eck,[50] Hindman[51] and others which I will review with more detail in Chapter LXXVI, devoted to a consideration of the treatment of neurosyphilis. This compound is apparently able to penetrate the tissues of the brain and cord and, according to Lorenz and his colleagues, is especially useful in conjunction with intramuscular injections of mercury salicylate in the treatment of early paresis, meningovascular syphilis, and, to a lesser extent, in taboparesis, tabes and advanced paresis. The drug is of no particular use, however, in the treatment of acute, early syphilis or other forms of chronic syphilis and its application is limited by the fact that it produces visual disturbances through involvement of the optic nerves in 7 to 23 per cent. of cases, as is so likely to be the case with the pentavalent arsenicals in general in contradistinction to the trivalent arsenicals like arsphenamin, neoarsphenamin and sulpharsphenamin which do not produce these toxic amblyopias.

Stovarsol is given by mouth in dose of 4 tablets (0.25 gm. each) usually with a little water before breakfast each day for 5 to 7 days; after a rest period of a week the course is repeated so that in a month as much as 12 to 16 grams have been given by Levaditi, Fournier and other French clinicians. This remedy however, is not free from unpleasant or even injurious toxic effects; moreover, its effect upon the various manifestations of syphilis, and especially on the Wassermann reactions, seems to be less than that of arsphenamin and its congeners. It is probable however, that the compound may prove of service when intravenous or intramuscular injections cannot be given and under these circumstances is worthy of trial.

Advantages and Disadvantages of Mercury in the Treatment of Syphilis.—The position of mercury in the treatment of syphilis is still upon the firm foundation of clinical experience. Threatened with dismissal by the discovery of salvarsan and ignored for a few years, it has since become again firmly established in the opinion of most syphilologists as indispensable and especially in the treatment of chronic syphilis. It is true that during the past ten years not a few reports have appeared stating that syphilis may be treated and cured by arsphenamin or its substitutes alone, but for every one physician of this opinion there are at least one hundred who are convinced that mercury should be given at some stage in the treatment of syphilis in all of its stages. Arsphenamin and its substitutes have not displaced mercury; they have simply proven additional and powerful weapons for treating syphilis and especially in its early stages. At the present time the position of mercury is again threatened by the advent of bismuth compounds, but in my opinion the newcomers will not displace mercury completely, although they are proving to be additional weapons at our command for combating syphilis and especially in the chronic stages.

Mercury is a spirocheticide, but is likewise so toxic that sufficiently large doses cannot be given at one time to produce the spectacular results of arsphenamin and its substitutes. For example, the largest dose of bichlorid

that can be given a syphilitic rabbit by intravenous injection is about 0.003 gm. per kilogram of weight, but I have repeatedly found that spirochetes disappear from scrotal and testicular lesions with about the same rapidity as when 0.003 gm. per kilogram of disodium arsphenamin is given intravenously. If we could safely give repeated injections of a rapidly dissociable soluble salt of mercury, like the bichlorid, intravenously in a dose even one-half as large as that of arsphenamin, the results would be just as pronounced as with the latter; but this, of course, is not possible on account of the high toxicity of the compound. It is true that the mercurial compound flumerin may be given in a dose as high as 0.005 gm. per kilo, which for an adult of average size corresponds to 0.3 gm. or one-half the usual dose of arsphenamin; but the results are not as good as a similar dose of the latter, because the mercury of this compound is not ionized as rapidly as in the case of inorganic salts like bichlorid. The high toxicity of mercury for the body constitutes, therefore, its great disadvantage. It requires that mercury be given in small repeated doses over a long period of time; it does not permit the administration of large sterilizing doses over a short time as is so easily possible with arsphenamin and its substitutes.

As a result, mercury cannot be given in sufficiently large doses to produce rapid spirillicidal effects. It is true that spirochetes disappear from lesions with healing of the latter, but the effects are not rapid enough in the majority of cases to prevent some of the organisms escaping destruction with subsequent localization in the internal organs and the production of chronic lesions. For this reason mercury is not the remedy of choice to-day for the treatment of acute early syphilis when rapid spirillicidal effects are demanded; the trivalent arsenicals arsphenamin and its substitutes are the remedies of choice at this stage with bismuth second and mercury third.

But mercury is of value in tertiary syphilis and why should this be so if it is so inferior in spirillicidal effects in the doses we may safely administer? An exact answer cannot be given except to state that clinical experience supports the statement. It is my belief that the reason is that mercury tends to accumulate in syphilitic tissues and exudates just as the iodids do in any syphilitic or non-syphilitic exudate; that because of this affinity of mercury for syphilitic tissues, it gradually reaches a concentration of spirocheticidal proportions without at the same time reaching toxic concentrations in the kidneys, liver and other important organs sufficient to interfere with their functions or with the elimination of mercury. To the best of my knowledge, this stored or accumulated mercury is still ionizable and therapeutically active, even though organic combinations may be produced with the cellular and humoral proteins. Arsphenamin and its substitutes, however, do not have this tendency for accumulation in syphilitic exudates, because arsenic does not have the same affinity although it may accumulate in the liver, bone marrow and other organs; or, if it does accumulate, it is rendered therapeutically inactive by processes of oxidation or reduction depending upon the nature of the compound with the same final result in either case, namely, therapeutically inactive pentavalent arsenic. In other words, the period of therapeutic usefulness of arsphenamin and its substitutes in the body is relatively brief; a few hours may be required to oxidize them into the spirocheticidally active oxids but unfortunately the process does not stop here: oxidation continues with the formation of compounds less active or inert. Arsphenamin, therefore, is like a "broom that sweeps," to quote Stokes, whereas faithful old mercury takes up residence in syphilitic foci in a fighting condition and is the weapon that "crushes" the spirochetes. Anything like a fibrous tissue barrier may prevent arsphenamin gaining entrance during its brief and fleeting

visit to the strongholds of the enemy; mercury is slower, knocks more persistently, is in no hurry to leave and finally gains entrance with death to spirochetes.

Others are of the opinion that mercury cures by stimulating immunity processes. No one expressing this view has to my knowledge substantiated the statement and as discussed at length in Chapter XXIV, I have not for myself been able to elicit evidence in favor of it. If mercury does act in this way, it probably does so by releasing antigenic substances from spirochetes which in turn engender the production of antibodies. Possibly our knowledge and technic are not sufficient at the present time for detecting the nature and degree of immunological changes, but for my own part I believe that mercury influences syphilis by the direct spirocheticidal effects of ionized mercury, as described above and in Chapter XXIV.

Naturally a very large number of different compounds and preparations of mercury have been advocated and employed in the treatment of syphilis; within the last two or three years various new organic compounds with dyes have commanded special attention like the mercury phthaleins, mercury-anthrachinons and mercury-azodyes studied by Hahn and Kostenbader;[51a] flumerin (the disodium salt of hydroxymercuri-fluorescein) described by White and his colleagues;[51b] a similar fluorescin-mercury compound described by Stuemer[51c] under the name of "Tachysan S;" a colloidal preparation of mercury amalgamated with gold described by Snodgrass[51d] and designated as "contraluesin," etc., but definite opinions of the value of some of them in the treatment of syphilis cannot be expressed at present.

The high toxicity of mercury is not to be mentioned as a disadvantage, except that it interferes with the administration of sufficiently large amounts at one time to duplicate the rapid mass spirocheticidal effects of arsphenamin; it is not, therefore, the remedy of choice in the treatment of acute early syphilis (primary and secondary stages). Its toxic effects are well understood and easily prevented, although some individuals will not tolerate it at all in therapeutic doses, but this is true of almost every other therapeutically worth while medicament for syphilis and other diseases as well. For the treatment of chronic syphilis in which mercury is still to be regarded as one of our most valuable remedies, it is usually possible to administer the compounds over long periods of time without injury to the patient.

Advantages and Disadvantages of Bismuth in the Treatment of Syphilis.—Compounds of bismuth are the latest additions to the family of remedies for the treatment of syphilis, being brought prominently before the profession in 1921–1922 by the laboratory investigations of Sazerac and Levaditi[52] and the clinical studies of Fournier and Guenot.[53] I have reviewed in Chapters XV and XXV the results of toxicity, trypanocidal and spirocheticidal activities, giving the main references to the literature. Since then a very large number of publications have appeared in France, Italy, Germany and Switzerland, with fewer in England and America, this large literature having been recently summarized by Levaditi[54] showing the curative activities of bismuth and especially the tartrobismuthates, in primary and secondary syphilis as well as in chronic syphilis and particularly neurosyphilis; it is not necessary, therefore, for me here to repeat this review which is very complete up to 1924. Since then, the reports by Klauder,[55] Hopkins,[56] McCafferty[57] and Shivers[58] have been noteworthy contributions from America.

My experience with bismuth has been confined entirely to potassium tartrobismuthate, sodium tartrobismuthate and the quartenary salt sodium and potassium tartrobismuthate. As would be expected a large number of newer compounds have already appeared, each with its usual claims of superiority. One of the latest of these, which I believe is worthy of special mention, is a bismuth nuclein compound reported upon by Fournier, Guénot,

Schwartz and Yovanovitch[59] because the combination with protein suggests that its administration may be accompanied by the spirillicidal effects of bismuth plus the non-specific protein reaction of the nuclein.

Weight for weight bismuth in the form of the sodium and potassium tartrobismuthate possesses in my experience about one-fourth to one-fifth the spirocheticidal activity of arsphenamin for rabbit syphilis, the single curative doses being approximately 0.050 gm. for bismuth and 0.012 gm. for arsphenamin (disodium salt) per kilogram of weight; contrary to popular opinion, it possesses only one-tenth the spirocheticidal activity of mercury. It is, however, twenty to forty times less toxic than mercury so that its chemotherapeutic index is at least five times higher, but weight for weight, bismuth is less spirocheticidal than either arsphenamin or mercury. However, owing to its lower toxicity we can administer much larger doses in the treatment of syphilis and this accounts for the impression that it is actually more spirocheticidal. For example, we may ordinarily give 0.2 gm. of the tartrobismuthates every 5 days for 15 doses or a total of 3.0 gm. before siderosis and other toxic effects appear; this corresponds to between 3 and 4 grains per dose or a total of 45 to 50 grains in a matter of 75 days, which is at least four to five times more than we give of mercury, since the dose is usually about 1 grain per week. In other words, mercury is about as toxic for body cells as it is for *Sp. pallida;* hence its chemotherapeutic index is only about 1, which constitutes its chief disadvantage. Bismuth, on the other hand, is about five times more toxic for *Sp. pallida* than for body cells; hence, its chemotherapeutic index is about 5 which constitutes its chief superiority over mercury. Arsphenamin is about 10 times more toxic for *Sp. pallida* than for body cells; hence its chemotherapeutic index is about 10. The best brands of neoarsphenamin and sulpharsphenamin are fourteen to eighteen times less toxic for body cells; hence their chemotherapeutic indices are 14 to 18. This tells the story of preference of compounds for the treatment of acute early syphilis when "sweeping" effects alone may suffice; undoubtedly the preference should be first for arsphenamin, neoarsphenamin or sulpharsphenamin; second, for bismuth and lastly, for mercury.

In the treatment of acute syphilis, either in the primary or secondary stages or acute progressive exacerbations of chronic lesions, bismuth would appear to be the medicament of choice if arsphenamin and its substitutes cannot be given on account of hypersensitiveness or other cause; this is because we may give safely larger doses of bismuth by injection than we may of mercury and thereby secure the next best rapid, mass spirocheticidal effects.

But what is the status of bismuth in the treatment of chronic syphilis? I doubt if this question can be fully answered at the present time; I know that my own mind is far from being clear on this point. In view of the fact that the chemotherapeutic index of bismuth is about five times higher than that of mercury in the way of single curative doses for rabbit syphilis, it would appear that the answer is apparent, but the treatment of chronic human syphilis presents problems that cannot be answered by experiments with either acute or chronic syphilis of the rabbit or monkey. I am of the opinion that bismuth exerts its curative effects by the spirocheticidal activity of the bismuth ion just as, I believe, mercury is curative by the spirocheticidal activity of the mercury ion. But we do not yet know if bismuth has any special affinity for syphilitic tissues as I believe mercury does; nor whether it is better able to penetrate fibrous tissue barriers and reach spirochetes. It is true, however, that clinical reports indicate an undoubted curative influence of bismuth upon tertiary lesions and especially in some forms of neuro-

syphilis as shown by Shivers, but I doubt the wisdom of substituting bismuth for mercury entirely in the treatment of chronic syphilis, even though one is tempted to do so since bismuth is so much less toxic than the latter. Furthermore, the oil suspensions of potassium tartrobismuthate or of sodium and potassium tartrobismuthate in dose of 0.1 to 0.2 gm. (2 to 3 grains) by intramuscular injection are so much less painful and so seldom produce tender nodosities as compared with 1 grain doses of any of the insoluble mercurials in oil, that patients very much prefer them and, indeed, a few refuse the mercury injections after once experiencing the greater comfort of the former. A review of the literature along with my own experience with intramuscular injections of oily suspensions of potassium tartrobismuthate and of sodium and potassium tartrobismuthate in doses of 0.1 to 0.2 gm. every five to seven days have lead me to formulate the following conclusions on the curative activity of bismuth in syphilis:

1. Spirochetes sometimes disappear from chancres within forty-eight hours after the first injection and almost always after 1 to 3 injections; chancres have usually healed within seven to twenty-one days.

2. Mucous patches in the mouth usually disappear very rapidly but the cutaneous secondary lesions more slowly and sometimes are so refractory that arsphenamin or neoarsphenamin must be administered.

3. The tartrobismuthates usually quickly heal open infectious lesions, but in my experience the action is not usually as prompt as follows the intravenous administration of 0.6 gm. of arsphenamin or 0.9 gm. of neoarsphenamin.

4. Tertiary lesions usually respond quite promptly and especially those of the skin and periosteum.

5. In some cases of neurosyphilis and especially cases of chronic syphilitic meningitis with persistent headache, the results are brilliant and frequently superior to those observed with mercury and the organic arsenical compounds. In tabes dorsalis the pains are usually promptly relieved by a few injections.

6. In congenital syphilis the lesions usually respond as promptly as under treatment with mercury or neoarsphenamin; cases of syphilitic epilepsy have been especially benefited.

7. Bismuth has proved especially useful in the treatment of syphilitic patients who are hypersensitive to arsphenamin, neoarsphenamin or mercury.

8. Bismuth is sometimes curative in cases of syphilis resistant to mercury and the organic arsenical compounds; in Wassermann-fast cases a form of combination theory with bismuth and an arsenical frequently yields better results than treatment alone with an arsenical or mercury compound.

9. Bismuth does not produce Herxheimer reactions as frequently as the organic arsenical compounds and is very useful for starting the treatment of chronic active or latent syphilis when "neurorecidives" and such exacerbations of syphilitic processes are feared and to be avoided.

10. Bismuth influences the Wassermann reaction more promptly than mercury but less promptly than neoarsphenamin and much less promptly than arsphenamin. In primary syphilis if treatment with bismuth is begun before the Wassermann test with serum yields a positive reaction, the reaction usually remains persistently negative indicating spirocheticidal activity.

To sum up, I believe that bismuth has established for itself a permanent place in the treatment of syphilis by reason of its low toxicity for the body associated with marked spirocheticidal properties; that it is especially indicated in the treatment of acute syphilis when arsphenamin and its substitutes cannot be given; that it is of value in the treatment of chronic syphilis and

especially of the central nervous system; that it is usually well borne when mercury is not and, therefore, serves a valuable substitute for mercury in chronic syphilis when the latter cannot be given in adequate dosage. Otherwise I am unwilling to use it as a substitute for either arsphenamin and allied compounds or mercury, until we know more of its final results. I believe, however, that it is worthy of use in the treatment of syphilis in all of its stages along with the organic arsenicals and mercury, as a form of combination therapy, which is the key note of success in the treatment of either acute or chronic syphilis.

Advantages and Disadvantages of the Iodids in the Treatment of Syphilis.—The great advantage of the iodids in the treatment of syphilis is their resolving influence upon organized syphilitic exudates or gummas. This is ordinarily so pronounced and especially on gummas of the skeletal system as to give the impression that the iodids are specific spirocheticides. On the contrary, they are not specific for syphilis since similar effects are sometimes observed in other infectious granulomas like sporotrichosis, blastomycosis and actinomycosis; neither are they strongly spirocheticidal since the iodids in the usual small doses are almost without destructive effects upon *Sp. pallida*. But they promote autolysis of gummas and less organized exudates and cause them to disappear more rapidly than in treatment alone with arsphenamin or mercury.

Some physicians still persist in treating cases of acute early syphilis by the iodids alone; some clinical improvement may follow, although Fournier has shown that the disease progresses through its usual stages with the production of tertiary lesions. There may be an excuse for treating some cases of tertiary syphilis with iodids alone because of their resolving action upon gummas, but there is absolutely no reason at all for using them alone in the treatment of acute, early syphilis; to do so constitutes a serious error.

When the treatment of syphilis is begun within eight weeks after the appearance of the chancre, there are no special indications for the administration of the iodids because there is no special work for them to do, since the exudates about the spirochetes are still cellular with no fibrotic changes in the blood-vessels; spirocheticides, as arsphenamin and its substitutes, mercury or bismuth may readily penetrate the exudates and reach the spirochetes. After the first few months of treatment, however, it is well to introduce the iodids for the purpose of aiding in reaching and destroying those spirochetes which have escaped destruction and brought about the laying down of fibrous tissue in the mesial coats of blood-vessels, perivascular spaces and inflammatory exudates.

When the treatment of syphilis is begun or resumed in the chronic stages of the disease, the administration of the iodids should constitute a very important part of treatment at the outset; I believe their administration should start with the first dose of arsphenamin, mercury or bismuth and persist throughout the course, being omitted during the rest periods since intermittent iodid treatment is better than continuous or unremitting medication. Even though there are no discernible gummas, yet the iodids doubtless aid in the removal of exudates of microscopic size in the different organs and more particularly in and about the walls of capillaries, thereby facilitating the access of spirocheticides, as arsphenamin or its substitutes, mercury or bismuth.

The iodids, therefore, have a place in the treatment of all cases of syphilis; in acute early syphilis during the first few months of intensive treatment with arsphenamin or its substitutes they may be omitted, since they serve no particular purpose at this time and may add to difficulties by producing toxic

reactions; but after this period, their administration is indicated and especially when gummatous deposits are seen or their presence in internal organs suspected by reason of symptoms and dysfunction.

The only disadvantages attending the administration of iodids are such toxic effects as the coryza, acne, etc. As stated in Chapter LVII, the iodids are not dangerous in the sense of producing tissue changes as the arsenicals, mercurials and bismuth compounds may produce upon prolonged administration. In this respect the iodids are eminently safe remedies. But it is to be remembered that the effects of iodids upon promoting the resolution of inflammatory exudates is not confined to syphilis and that their administration to tuberculous individuals may result in the breaking down of tuberculous lesions with dissemination of the bacilli; therefore, they must be used with great caution, if at all, when advanced tuberculosis is known to be present.

CHAPTER LXVIII

NON-SPECIFIC PROTEIN THERAPY OF SYPHILIS

Non-specific Drugs in the Treatment of Syphilis.—In view of the high toxicity of mercury and the severe toxic effects sometimes produced by the administration of excessive amounts, it is but natural that many vegetable drugs have been advocated from time to time in the past as substitutes for the treatment of syphilis. But none have gained a place in the modern treatment of this disease although it is possible that intramuscular and intravenous injections of various vegetable proteins may prove of service, as would appear to be the case with proteins of animal origin, like intramuscular injections of sterile milk.

Probably the best known and most valuable of the non-specific drugs in the treatment of syphilis are the iodids. As ordinarily administered, these compounds are not specific in the sense of being sufficiently spirocheticidal to cure syphilis by killing spirochetes, as has been discussed in Chapter XXVI. Their feeble spirochetal activity has been abundantly shown in experimental syphilis and is confirmed clinically by the feeble curative activity of the iodids in the treatment of syphilis in its primary and secondary stages, as well as by the very high incidence of tertiary lesions in cases of syphilis treated exclusively with the iodids. But no one can deny their great value in the treatment of chronic syphilis by their influence upon the products of syphilitic infection, namely, in stimulating the autolysis of organized or fibrotic syphilitic exudates. The iodids, therefore, are not truly specific in syphilis; they are wonderfully curative non-specifics too frequently forgotten now-a-days in our concentration upon the specifics. They afford symptomatic relief when used alone; when administered along with specifics as the arsphenamin and mercurials, they aid in addition to bring about the destruction of spirochetes.

Non-Specific Protein Agents in the Treatment of Syphilis.—But non-specific therapy in syphilis refers more especially to the administration of agents capable of producing fever, leukocytic and enzymic changes, increase of capillary permeability, etc., and within recent years several publications

have shown that various non-specific agents may favorably influence the treatment of syphilis. I refer especially to *intramuscular injections of milk and milk preparations, subcutaneous injections of tuberculin, subcutaneous injections of luetin, including, possibly, the inoculation of paretics with malaria and relapsing fever*, etc. Schacherl[1] has reported that cases of syphilitic neuro-arthropathies and various types of neurosyphilis appeared to be benefited more by combined treatment with tuberculin and mercury than by mercury alone; the Wassermann reaction appeared to be much more rapidly changed and the mercury (salicylate) appeared to be absorbed more rapidly. Schreiner,[2] Uddgren,[3] and others have noticed that the Wassermann reaction became negative much sooner in cases treated with injections of milk and peptone along with specifics than by specifics alone and I have already referred to these observations in preceding chapters. Kryle[4] has reported favorably on the effect of combined non-specific protein and specific antisyphilitic medication in reducing presistently positive Wassermann reactions and Fischer[5] has especially advocated this type of treatment in paresis and tabes dorsalis, which he designates as "phlogistic therapy."

More recently, Ahlswede[6] has found that intragluteal injections of 10 c.c. of a sterile milk protein solution at intervals of about ten days were useful as supplements to specific spirocheticide therapy in the way of general non-specific protein stimulation of the body. Greenbaum and Wright[7] have likewise observed that intramuscular injections of 5 to 6 c.c. of a 4 per cent. suspension of milk proteins every two to three days for six injections were alone capable of influencing tertiary skin and mucous membrane lesions, bringing about their resolution and disappearance unaided by specific medication. Starcke[8] has recently described a method for the treatment of paresis consisting of the intramuscular injection of common boiled milk in the morning which he states produced a mild fever by evening when massage is given and neoarsphenamin administered.

Muller and Pfanner[9] have recorded a case of syphilis refractory to specific treatment alone that yielded promptly to combined injections of *luetin* and neoarsphenamin. Some years ago Dr. Schamberg and I treated a series of Wassermann-fast cases of syphilis with combined injections of *luetin* (subcutaneously) and arsphenamin (intravenously) and gathered the impression that the results were better than observed with injections of arsphenamin alone; unfortunately, our supply of *luetin* at the time did not permit a sufficiently extensive trial to warrant a more definite statement. Finally it may be stated that a rather large literature has accumulated upon the treatment of paresis in Europe by inoculations of living tertian malarial parasites or the spirochetes of relapsing fever, the paroxysms being found distinctly helpful in the treatment, along with specific medication, as discussed more fully in Chapter LXXVI.

Of course, the treatment of paresis with malarial inoculation may not be a form of non-specific medication in the usual meaning of the term. Ordinarily we regard injections of milk, peptone and other protein agents as aiding in the treatment of infectious diseases by producing fever, leukocytosis and increasing the enzymes and antibodies of the blood and fixed tissues. Malaria produces fever but scarcely any leukocytosis; but similar reactions produced by injections of milk, protein, etc., have not given as good clinical results; neither have inoculations with *Sp. obermeyerei* (relapsing fever), suggesting that the living malarial protozoa furnish something inimical to syphilis by a mechanism not understood at present and analogous to the effects of erysipelas and other streptococcus toxins (as contained in Coley's fluid) upon sarcomata.

Value of Non-specific Protein Therapy in Syphilis.—No one, however, would seriously consider depending upon non-specific agents alone for the treatment of syphilis. From experiments on rabbits I am convinced that injections of milk, milk proteins, peptone and *luetin* have no effects upon the spirochetes in the way of direct spirocheticidal activities; Greenbaum and Wright have also observed that intramuscular injections of milk proteins were practically without curative effects in acute early syphilis. *On the contrary, injections of non-specific protein agents may actually stimulate spirochetic activity,* as I have observed in some instances of scrotal and testicular syphilis of rabbits; for this reason I believe that *when these agents are employed in the treatment of human syphilis that there should be the simultaneous administration of spirocheticidal drugs,* just as in the case of the iodids, not only to secure the maximum therapeutic effects of the latter, but to prevent exacerbation and dissemination of syphilis as well. These agents may stimulate immunological processes in syphilis and especially proteolytic activity in organized syphilitic exudates, as shown by their autolysis in a manner similar to the action of the iodids. It appears that the effects are due in part to the vascular changes produced embracing congestion and increased capillary permeability. I am particularly interested in the possibilities of subcutaneous injections of *luetin* in this connection by reason of the possible allergic vascular changes that may be produced and thereby increasing the access of spirocheticide agents and enzymes to the infected tissues. Enough has already been done to show that carefully chosen and skilfully administered non-specific protein agents may be helpful in the treatment of some cases of chronic syphilis as adjuvants in treatment and especially in neurosyphilis; indeed, it is quite probable that the increased curative activity of arsphenamin and its congeners by subcutaneous or intramuscular injection, as compared with intravenous injection, may be due in part at least to the effects of local tissue necrosis releasing stimulating protein agents and the same may be true of intramuscular injections of mercury and bismuth. I have observed clinically that this form of adjuvant non-specific protein therapy was particularly useful in the treatment of chronic syphilis accompanied by debilitated states and especially tabes dorsalis; the nutrition has appeared to be improved with an increase of weight, erythrocytes and hemoglobin, to which further reference will be made in Chapter LXXVI, where the literature is reviewed with more detail.

Administration of Non-specific Protein Agents in the Treatment of Syphilis.—Up to the present time this form of therapy in syphilis has been largely confined to paresis and tabes dorsalis. Various agents have been employed as mentioned above. Fischer has employed plant albumins rich in nucleoproteins broken down into polypeptids ("phlogetan"); Ahlswede has employed milk proteins as likewise Greenbaum and Wright. The preparation should not produce too sudden or severe reaction and too many injections should be avoided in order to avoid a "proteinogenous tiring" or "proteinogenous cachexia" from over stimulation.

Fischer advises that an energetic course of specific medication should precede the non-specific treatment but Ahlswede apparently favors mild non-specific medication first to be followed by specific medication with iodin and bismuth preparations. In paresis he injects 1 c.c. of a 10 per cent. solution of milk proteins intramuscularly and states "if the increase of the leucocytes, the increase of the red cells and of the hemoglobin content, the increase of the blood platelets and of the sinking rapidity of the erythrocytes point to a strong reaction, the dose administered may be repeated after 3 to 4 days. Should no reaction occur the initial dose would have to be increased.

If the initial reaction is very strong it is advisable to choose a longer interval between the following injection, and also to reduce this second dose. As a rule five injections will prove sufficient (Fischer who uses "phlogetan" injects up to 10 c.c.). Treatment must be interrupted in all cases in which a sudden drop of the leucocytes and the platelets takes place. During the intervals, between the last (fourth and fifth) injections I advise beginning internal medication of iodine and bismuth injections, which should be carried on for a few weeks under permanent control of the blood picture. After 4 to 8 weeks' interval, according to the general constitution of the patient, a second "course" should begin with or preferably without specific simultaneous medication. These "courses" should follow one another in a regular sequence till the clinical improvement is obtained."

Intramuscular injections of milk (boiled for ten minutes and cooled) may be employed in doses of 1 to 10 c.c.; for sharper reactions vaccines of colon or typhoid bacilli may be injected intravenously in dose of approximately 100,000,000 organisms or sterile 2 per cent. solutions of peptone may be administered by slow intravenous injection in dose of 1 to 3 c.c. My own experience has been limited to injections of milk in dose of 2 to 5 c. c. for the purpose of producing mild stimulation in the treatment of undernourished tabetics.

CHAPTER LXIX

HYGIENE AND GENERAL TREATMENT OF SYPHILIS

While specific medication in syphilis is naturally of first importance, general or auxiliary treatment and hygiene should not be neglected, and at the present time they do not receive the same attention as formerly when the mercurials and iodids were relied upon exclusively for specific treatment. It is necessary to inquire into the general health of patients; to observe their temperament and pay due attention to their general hygiene as the details of their mode of living, diet, occupation, the time devoted to exercise and sleep, etc. We should make our patients understand the necessity of a quiet and regular life, free of excesses of any kind. In certain nervous patients, especially women, these auxiliary medications are sometimes of great importance, the state of the functions and general health requiring supervision and treatment as well as the syphilitic infection.

General Hygiene.—Not infrequently the syphilitic requires advice on such subjects as sufficient and proper *exercise* to maintain physical fitness, plenty of *fresh air* and an adequate amount of *sleep*. The latter and a quiet normal life, free of undue physical and mental fatigue and excitement, are of

special importance in relation to invasion and infection of the central nervous system. As discussed in Chapter XXXVI mental strain and overwork undoubtedly favor infection of the central nervous system with *Sp. pallida*. It is well to impress the syphilitic patient that relapses and lesions may follow tissue injuries and shocks, undue exposure, or overstrain, physical or mental. The importance of avoiding these must be recognized, whether in private or business life.

Tabetics and others physically incapacitated derive great benefit from *massage* and *electricity* is frequently helpful and sometimes a valuable supplement to inunctions of mercury where nerve symptoms are prominent. The pains of tabes are sometimes relieved by either the static or high frequency currents, the former being more suitable when the blood pressure is low and the latter when it is raised.

Sexual excesses must be especially avoided, because of physical and mental depletion. During the infective stages sexual congress must, of course, be strictly forbidden.

Oral Hygiene.—The mouth requires special attention. Since the advent of the organic arsenicals in treatment, we are apt to over-look the importance of this subject, since stomatitis is not so likely to occur as in the days when mercury was employed more freely in treatment. But, as stated in Chapter LI, it is quite possible that some of the severe accidents of arsenical therapy are due to the lighting up focal infections, and the removal of tartar and stumps, the filling of cavities, etc., are of just as much importance in relation to the administration of arsphenamin and its substitutes as they are to mercury and bismuth, which are more likely to produce buccal accidents. It should be an invariable rule of practice to inspect the mouths of every syphilitic at frequent intervals and to insist upon proper dental supervision and care, with cleansing of the gums and teeth at least once or twice daily with good brushes and dentifrices. It is my practice to insist upon each patient consulting his dentist at the beginning of treatment and at intervals of six months thereafter during the years he is under observation and treatment. If open lesions are present in the mouth, I insist upon the patient informing his dentist of the syphilitic infection, as their character may not be recognized by him, to the possible danger of himself and others.

Mental Hygiene.—As so correctly stated by Fournier even in the days before the discovery of *Sp. pallida*, "an organ which is stimulated or overworked in a syphilitic is an organ which is menaced by syphilis, for stimulation tends to direct the disease to this organ. Cerebral syphilis is especially common after nervous and intellectual overwork, and still more so after excitement, late hours, and dissipation, the excitement of play, venereal excesses, etc."

As clearly shown by him clinically and confirmed in recent years by laboratory examinations, the nervous system is the most often affected by tertiary syphilis. I have already discussed in Chapter XXXVI the question of strains of *Sp. pallida* in reference to this subject and expressed the opinion that hereditary predisposition and neuropathic tendencies are more important than the question of strains of the organism. Individuals of these groups who have contracted syphilis should be cautioned at the outset against all possible causes of morbid stimulation of the nervous system, such as excesses of all kinds, and especially venereal excesses, intellectual work requiring continuous mental strain, fatigue, late hours, excessive emotion or business worry and even too violent bodily exercise. Indeed, what may be called *antinervous treatment* is especially indicated in individuals belonging to these two classes.

The majority of syphilitics are subject to mental depression and excessive worry regarding the disease and prognosis. Indeed, as Collins has so well stated, it may be impossible to cure the syphilitic "scars of the spirit," but these must be combated by suggestion and an optimistic outlook on the part of the physician. I firmly believe that we may honestly feel optimistic in the treatment of the majority of syphilitic patients and I do not hesitate to take sufficient time to express a full, candid and detailed description of the disease to meet individual cases and the general outlook. It is a mistake to make light of the patient's fears and symptoms, regardless of how trivial they may appear. To him or her they are of great importance and worthy of our sympathetic hearing and attention. On the other hand, the too cheerful and careless patient must be convinced of the seriousness of his condition. In other words no one method of handling this phase of the treatment is applicable to all patients; the physician must decide upon the proper attitude for each case, since the best method for one may be harmful for another.

Hydrotherapy.—This naturally brings up the subject of hydrotherapy in the treatment of syphilis of the nervous system as well as in relation to syphilis in general. Fournier was a warm advocate of this auxiliary treatment on account of its tonic and regulating action on the nervous system. He regarded its preventive action as equal to its curative effect in the treatment of affections of the nervous system and was in the habit of prescribing it to all syphilitic subjects who, by their hereditary predisposition or their personal tendencies, lead him to regard them as predisposed to the nervous manifestation of syphilis.

As stated in Chapter LIII, evidence at hand indicates that the ingestion of sulphur waters aids in protecting against the effects of mercurialism and, as mentioned in Chapter LI, it would appear that the administration of sodium thiosulphate and thiosinamin are useful in the treatment of arsphenamin dermatitis and allied reactions. Physicians of experience in certain watering places in Europe and America are frequently convinced that their patients are able to stand much larger doses of mercury by inunction than would otherwise be the case and especially elderly tabetics of poor nutrition; this is especially true at Aachen where the water contains small amounts of hydrogen sulphid, sodium sulphid, sodium iodid, sodium bromid as well as larger amounts of sodium chlorid, sodium carbonate and calcium carbonate. It is believed that the ingestion of this water results in the greater elimination of mercury with the promotion of diuresis and catharsis, resulting in an increased excretion of urea and sulphates in the urine and increased elimination of the skin with stimulation of the appetite, improvement of digestion, increased excretion of bile and general tonic effects.

Many syphilitics and especially the elderly who do not bear mercury well, fair much better at the Hot Springs of Arkansas in this country than in their homes; the good effects have been ascribed to a specific action of the water, both as baths and taken internally, to greater elimination, to stimulation, to the routine life, and to the effects of the salubrious climate. The alleged effects of the water have been ascribed to some peculiar chemical combination of the solids in solution, to electricity produced by chemical decomposition, to heat, and latterly to radio-activity. Loyd Thompson, practicing at the Hot Springs, does not believe that the waters have any specific influence upon *Sp. pallida* and has summarized his opinion[1] on their general effects as follows: "It is a fact, however, that patients bathing in these waters are able to take much more mercury without any untoward effects than others. It is furthermore highly probable that some of the bene-

fits derived are due to increased elimination of the products of catabolism. To these benefits derived from the increased ability to take mercury and the increased elimination must be added the benefits derived from the regular life the patient usually leads, the outdoor exercise, the freedom from business cares and worries, and finally, the fact that the average patient who comes to this or any other resort follows the physicians' directions more implicitly than when at home; in short, makes a business of getting well.

"While each case of syphilis is a law unto itself in regard to bathing as well as in other features, the following may be said to be fairly representative of the usual method of administering the baths to syphilitics in this resort:

"The patient is placed in a tub of hot water at a temperature of 35.5°C. to 38°C. (96°F. to 100°F.) where he remains from eight to fifteen minutes. When free diaphoresis is desired he is placed in a hot wet pack and covered with blankets for fifteen to thirty minutes, and when more profuse sweating is wanted the vapor cabinet is used for three to five minutes. Usually in the tub and in the pack the hot water is taken to drink to assist in promoting diaphoresis. Generally following the pack a shower and needle is given for two or three minutes beginning at a temperature of 38°C (100°F.) and being reduced to 32°C. or 27°C. (90°F. or 80°F.). Following this the patient sits or lies in the cooling room until cool and the skin is dry. Ordinarily the patient spends from one and a half to two and a half hours at the bath house."

Not all patients, however, can stand the expense of a sojourn from home and business, but it is sometimes possible to approximate this plan at their homes by using ordinary water with great benefit and especially in neuro-syphilitics of advanced years who are under weight, who need mercury and bismuth, but who do not tolerate sufficient doses of the drugs.

General Medication.—In addition to medicinal aid for the correction of constipation, the administration of stomachics and so-called "tonics" may be especially helpful when the appetite is poor and the patient under weight; Thompson prescribes the following:

℞ Tr. nuc. vom. ..... 45.0 c.c.
Tr. cardamon comp.
Glycerin ..... āā 90.0 c.c.
Aq. destil. ..... q.s. ad 240.0 c.c.

One to two teaspoonfuls in water are prescribed before each meal.

As a general rule the anemia of syphilis responds promptly to the administration of arsphenamin and its substitutes; iron is of no particular value. The organic arsenicals also frequently afford great relief to the emaciation and other untoward effects of mercurialization.

Diet.—In the fifteenth and sixteenth centuries, great attention was given the subject of diet in syphilis and other diseases. Depending upon the fads and fancies of the times patients were either starved or over-fed and the diets were made out with great care, so many foods being forbidden that one wonders how the victims survived. It is now well known that no foods are particularly favorable or unfavorable to syphilis, although, when mercury is being given, due attention must be paid to the diet to reduce to a minimum the chances of producing gastro-intestinal disturbances. Therefore, if the usual diet of the patient is good, it requires no change; if it is insufficient or defective, it requires suitable modification and if excessive, reduction to hygienic proportions. Excessively stout and florid individuals with high blood pressures generally overeat and exercise too little; these faults should receive attention. Thin, emaciated and anemic individ-

uals and especially elderly tabetics require overfeeding, rest and massage as auxiliaries to specific medication. In syphilitic nephritis and in gastric and liver syphilis, special attention must be given the diet as likewise syphilitic infants and children, the former sometimes presenting unusual difficulties when fed artificially.

When arsphenamin or one of its substitutes is being administered by intravenous injection, it is well for the stomach to be empty; the preceding meal should be light and taken at least two hours previously, to minimize the chances of producing nausea and vomiting. When intramuscular injection of sulpharsphenamin, bismuth or mercury are being given, these precautions are not important.

When patients show a tendency for developing diarrhea and colic after the administration of the arsenicals, mercurials or bismuth compounds, the diet should receive special attention; under such circumstances iced drinks, uncooked vegetables and fruits and especially salads may require reduction or omission, whereas milk and foods prepared of milk may be given more freely. Due care must be taken to exclude such foods for which the patient shows allergic hypersensitiveness or idiosyncrasy; women especially are apt to rebel against eggs.

Beverages.—Fournier has stated that alcohol is the born enemy of the syphilitic and constitutes a serious factor, both in a general way and in relation to certain special lesions, such as the dermatoses and manifestations of the nervous system. Most syphilologists warn against even small amounts of alcohol as being detrimental and especially moderate drinking all the time rather than a spree once or twice a year.

Constipation should always be corrected and the subject is worthy of special attention in women patients; practically all of the specific remedies are eliminated in part through the bile and intestinal canal and due care is required to prevent reabsorption. It is commonly stated that alcoholics are more susceptible to the untoward effects of arsphenamin and its substitutes, probably as a result of cardiovascular changes and especially of the vessels of the kidneys. Possibly, too, the metabolism of the alcoholic individual favors the production of toxic products of the drugs in the organs and tissues to a greater extent than in non-alcoholic persons.

As in everything else, however, common sense is required in giving advice on the use of alcoholic beverages. As a general rule they should be forbidden, but the elderly and undernourished may require small amounts of wine or other light alcoholic beverages once or twice a day at meal times. I have not observed any harm from alcoholic beverages in strict moderation under such circumstances.

Coffee and tea in moderate amounts are not harmful provided gastro-intestinal disturbances are absent. An excess of either, however, and especially in cases showing nervous manifestations, should be forbidden. As a general rule the free and liberal use of water, milk, butter-milk, etc., should be encouraged.

Tobacco.—Smoking, and especially excessive smoking of strong tobaccos, is harmful for many syphilitics, as shown by the high incidence of tongue and buccal lesions among men as compared with women. When lesions are present in the mouth, tongue or throat, I believe that smoking and chewing should be absolutely forbidden or greatly curtailed. Given a syphilitic glossitis plus smoking and the tissues are well prepared for cancer. In the absence of manifest lesions, moderate smoking may be allowed, but I believe it is always the duty of the physician to carefully explain to the patient that smoking greatly increases the chances of producing lesions of the lip, tongue

and throat that may eventually prove of serious import. This is due to the fact that tissue irritation and injury always predisposes to the localization and multiplication of *Sp. pallida.*

CHAPTER LXX

CHEMICAL PROPHYLAXIS OF SYPHILIS

With a disease as infectious as syphilis, it is not surprising that many methods have been advocated for reducing its incidence. These may be divided into those that may be taken by the individual, and those that may be taken by the community. A great deal of discussion has been raised on the moral aspects of methods for the prophylaxis of syphilis on the basis that to make exposure safe is to increase immorality, but I shall not enter upon this subject since very complete and splendid discussions have been published by Fournier[1] and more recently by Vedder[2] and Stokes.[3] Neither shall I consume space in a discussion of community or public measures for the suppression of syphilis and other venereal diseases by the suppression or regulation of prostitution, etc.; nor upon the use of circumcision or mechanical devices for individual prophylaxis, but devote myself to a consideration of the subject of chemical or medicinal prophylaxis against genital and extragenital syphilitic infection to be applied within the first few hours after contamination and possible infection. The subject of abortive treatment, that is, treatment in the incubation period between the time of infection (exposure) and the development of the chancre, is considered in the succeeding chapter.

Individual Chemical Prophylaxis of Syphilis and Other Venereal Diseases. Individual chemical prophylaxis refers to the use of various substances by the individual before or after sexual contact or extragenital contamination for the prevention of infection by the destruction of spirochetes deposited on the skin or mucous membranes or in abrasions of these before infection has occurred or within a few hours thereafter. Probably one of the earliest attempts in this field was made by Fallopius, published in his book, "De Morbo Gallico," printed in 1564, and recently reviewed by Lane.[4] Fallopius advised washing the parts immediately after exposure and placing over the glans penis a piece of cloth impregnated with gentian, santal wood, aloes and other substances and claims that he tested this in one thousand, one hundred cases with no infection! As stated by Lane, some of his successors in syphilology have been inclined to question his veracity and that it is safe to assume at least that he probably did not have one of our modern, efficient follow-up systems at his disposal!

According to LePileur,[5] Agato at about the same time used fumigations of cinnabar and Desault is said to have advocated the use of mercurial ointment in 1733, reasoning that if mercury cures syphilis it ought to prevent it as well. During the following 160 years, these methods do not appear to have commanded much attention; in 1899, however, Behrmann,[6] Cohn,[7] Richter,[8] Loeb,[9] Guiard[10] and others greatly renewed interest in the subject by the reports of uniform success among men following applications of mercurial ointment, bichlorid of mercury, etc., to the penis immediately after coitus with syphilitic women.

Prophylaxis in Experimental Syphilis.—But after the discovery in 1902 by Metchnikoff and Roux,[11] that syphilis could be transmitted to chimpanzees, interest in the subject of prophylaxis was greatly renewed by their experiments employing mercurial ointment and later a salve of 10 parts of calomel and 20 parts of lanolin. In 1906 they reported[12] that, having tried twelve experiments on monkeys with uniformly successful results, they performed an experiment on a volunteer medical student (M. Maissonneuve) with complete success. Naturally these experiments attracted wide attention and in most quarters there was a tendency to accept them as a solution of the problem of the prophylaxis against syphilis. Levy-Bing,[13] however, claimed that the evidence was not conclusive and recorded a failure in a case of Gaucher's and additional occasional failures were soon recorded, the most severe critic of calomel ointment being Neisser,[14] who conducted a very large series of experiments upon apes with the result that inunctions and washes did not regularly prevent infection. Neisser showed, however, that simple washing with water for fifteen minutes prevented the infection of two apes and success was also observed with pure phenol, 1:2000 to 1:3000 bichlorid, 5-per cent. silver nitrate and 10- to 30-per cent. suspensions of calomel in soap, vaseline and saline solution; failures followed the use of iodoform, mercurial ointment, bichlorid 1:1000 and 10-per cent. suspensions of calomel. Metchnikoff,[15] however, promptly pointed out that Neisser's failures were with 10-per cent. calomel preparations and not with the 33-per cent. ointment which he recommended; in a second series of experiments with seven monkeys, he showed that the calomel must be at least of 25-per cent. strength and recommended 33-per cent., stating that "experiments on the preventive action of mercurial ointment on monkeys are sufficiently numerous and conclusive to form a basis of a prophylaxis against syphilis." Vorberg[16] believed that Neisser's failures may have been due to too deep scarifications, which may readily prevent access of the calomel to the spirochetes. However, Neisser was not opposed to the method; indeed, he was a warm advocate of it, but maintained, after another very extensive series of experiments with apes in collaboration with Seibert,[17] that bichlorid of mercury was superior to calomel ointment because he found calomel less spirocheticidal *in vitro*, and that its activity was much reduced because of its incorporation in a fatty base. Neisser recommended a mixture of starch, tragacanth, gelatin and mercuric chlorid, because he believed it a more powerful spirocheticide, more likely to adhere to damp and abraded surfaces and more successful in preventing infection. This naturally led to considerable investigation on the comparative bactericidal activity of various germicides in solution and in salves, with the general result that the former were found more effective, but the results did not apply to calomel which is practically insoluble in both. As previously stated, Metchnikoff prepared his ointment by mixing 10 parts of calomel with 20 parts of ordinary lanolin (not anhydrous); in the U. S. Army the following mixture has been employed:

Calomel	30 parts
Benzoinated lard	65 parts.
White wax	5 parts

Recently Nichols and Walker,[18] working with inoculated rabbits, found that this ointment proved efficacious up to eight hours after inoculation with syphilis and that no marked difference appeared between the action of calomel in a base of lanolin and vaseline and in a base of benzoinated lard and wax.

Animal experiments have, therefore, conclusively proved the prophylactic value of calomel ointment and despite Neisser's vigorous protests (he appeared to be somewhat biased in his opinions), it has been employed much more widely than solutions of bichlorid or other substances, notably quinin ointment advocated by Schereschewsky[19] and others, dusting powders of sodium and potassium tartrobismuthate by Levaditi,[20] etc. As stated by Vedder, bichlorid solutions are open to serious objection on the basis of high toxicity and furthermore, they dry so quickly that their spirocheticidal action is probably of briefer duration than is the case with calomel ointment. It is true that Schumacher[21] and others have recently sought again to discredit Metchnikoff's claims, but the evidence from animal experiments is overwhelmingly convincing. In Chapter XXVIII I have shown the high spirocheticidal activity of mercury *in vitro* and the experiments of Neisser and Seibert, consisting of mixing emulsions of syphilitic spleen, testicles and bone-marrow of apes with various solutions of bichlorid and calomel, followed by inoculating the material into apes to determine the degree of spirocheticidal activity *in vitro*, have likewise shown the powerful effects of these substances when brought in contact with virulent spirochetes. In their experiments water and salt solution alone were without effect, but 1:5,000 to 1:10,000 solutions of bichlorid and 10-per cent. suspensions of calomel in saline and oil were generally effective when allowed to remain in contact with the spirochetes for at least fifteen minutes before inoculation. My experiments employing rabbits have yielded similar results and, since the publication of the article by Nichols and Walker, I have been able to confirm their work on the prophylaxis of syphilis in rabbits with calomel ointment in every essential particular. It is true that failures have occurred, but I believe these were due to too deep

scarifications, excessive oozing and bleeding and such fortuitous circumstances preventing the contact of calomel with the organisms; personally, I am convinced of the extremely high prophylactic activity of 33-per cent. calomel ointment in experimental infections when applied within four hours after inoculation. Furthermore, a very large literature has accumulated on the subject as applied to human beings exposed to syphilis, which is likewise convincing despite isolated failures.

Prophylaxis in Human Syphilis.—It is not profitable, however, to attempt analyzing all of this literature here, because many of the reports will not stand an impartial scientific scrutiny of the results, although their authors were personally convinced of the correctness of their results and conclusions. Metchnikoff,[22] Wolbarst[23] and others, however, have reported individual cases of protection almost as convincing as experiments with the lower animals, although apparent failures have likewise been reported by Butte,[24] Gaucher,[25] Carle,[26] Sutton[27] and others. Probably the statistics furnished by Army and Navy surgeons are the most valuable of all, because it is possible to study the subject in these services under much better conditions than in civilian practice. The reports of Acevedo[28] in the Chilean navy, Feistimantel[29] in the Hungarian army, Tandler[30] and Seibert[31] in the German army and navy, Michels,[32] Wickes,[33] Davidson,[34] Ledbetter,[35] Ashford,[36] Cottle,[37] Riggs,[38] Exner,[39] Reynolds and Wolfe[40] and others in the United States army and navy, have shown in a convincing manner that syphilis undoubtedly can be prevented by the use of various prophylactics, and particularly by the use of 33-per cent. calomel ointment.

It has been noted that a delay of more than four hours in applying prophylaxis results in a considerable jump in the incidence of infections although the incidence after a delay of even 10 hours was doubtless much less than among cases receiving no prophylactic treatment at all. Probably the best statistics have been furnished by Colonel Wolfe, from Fort McKinley, P. I., for the period from January, 1913 to August, 1915; during this time treatments were given 19,465 times with but 2 cases of primary syphilis, whereas 99 cases developed among men who did not take the calomel prophylactic.

Limitations and Value of Chemical Prophylaxis in Human Syphilis.—I believe we may conclude from the experimental and practical work with venereal prophylaxis that syphilis, gonorrhea and chancroid undoubtedly can be prevented in the majority of instances by the use of appropriate prophylactic measures. Calomel is highly bactericidal for the gonococcus and *B. ducrey* (chancroid) as well as for *Sp. pallida;* the application of 33-per cent. ointment may, therefore, protect against both syphilis and chancroids, while a suitable silver salt like argyrol or protargol, is injected into the urethra for the destruction of gonococci. In practice it cannot be expected that their use will be invariably successful, but it appears that when properly applied within one to four hours after exposure that they will prevent the great majority of syphilitic infections. Experience in the army and navy has shown that good results can only be expected from the use of prophylactic measures when the medicinals are provided and when medical and other authorities unite to instruct the men in their value and the method of use.

One may very properly inquire if calomel ointment or other medicinal prophylactics destroy all spirochetes at the site of application and thereby actually and truly prevent syphilitic infection, in the true sense of the term, or merely reduce them in numbers or virulence to such an extent that a primary lesion is not produced or escapes detection while the lymphatic system is infected with the subsequent development of lesions. I am confident that prophylaxis can be made complete in the strictest sense, in

rabbits at least, because frequent tests with excised lymph-glands have yielded negative results when emulsions were injected into the testes of fresh animals; furthermore, most clinical observers, especially in the army and navy, have had a sufficient number of men under observation along with repeated Wassermann tests with absolutely no clinical or serological evidences of infection, to warrant the statement that these measures may be relied upon *when properly applied* as truly prophylactic for syphilis in the strictest application of the term.

One of the most important phases is thorough cleansing of the parts and the application of the prophylactic within an hour after exposure; the lapse of more than four hours reduces the chances of success quite materially. This is a point worthy of considerable emphasis, as not infrequently men delay in applying the prophylactic too long or repeatedly expose themselves over a period of six to twelve hours or more before applying the measures after the last exposure which reduces the chances of affording protection after the first exposure.

The method has not been extensively applied to women because of the anatomical difficulties, but there is no reason why it should not be tried when syphilitic infection is suspected; failure, however, occurs much more frequently than in men.

The method has likewise failed in deep inoculations with syphilitic virus as the pricking of the fingers with needles, etc., by surgeons. Under such circumstances very thorough cleansing and application of calomel ointment may be tried, but when there is great danger of infection and much worry, I believe it is well to follow up these with at least three injections of neoarsphenamin, which I have discussed in the succeeding chapter with more detail.

Furthermore, *the prophylactic is only of value to the parts treated.* I have known two men, apparently escaping genital infections as the result of calomel prophylaxis, who contracted syphilis of the lips from kissing their sexual partners who had mucous patches in their mouths. It is important to remember in this connection, that the prophylactic should be applied to the lips as well, after contact with a syphilitic with open lesions about the lips or in the mouth.

Sexual contact with a Wassermann positive woman with chronic, latent syphilis but without open lesions, is not likely to be followed by infection, unless frequently repeated, although small abrasions may be present in the vaginal and cervical mucous membranes easily escaping detection. For this reason prophylaxis should always be resorted to if possible, regardless of the question of probable absence of open lesions.

Men with chronic syphilis with no open penile lesions are not nearly so infectious as when a chancre is present, although the semen may be infectious. It is not to be forgotten, however, that women may escape infection after sexual contact with men having penile chancres, as recently reported by Troisfontaines,[41] but I always suspect in such cases that the woman may be already syphilitic with the possible protection against superinfection given by the presence of living spirochetes in her tissues.

Method of Applying Genital Prophylaxis in Men.—(1) As shown by Worms[42] and others, the application of prophylactic before intercourse is not as efficacious as post-coital application. However, preliminary application of the ointment is advisable, if for no other reason than that lubrication reduces the chances of producing abrasions.

(2) As soon as possible after coitus the parts should be thoroughly washed with soap and water. As shown by Reasoner,[43] a solution of soap of even

a considerable degree of dilution, and a lather as used in shaving, may be sufficient for destroying *Sp. pallida* and it is probable that chancroidal infection may be also avoided by the same means.

(3) The parts may now be rinsed with water followed by thorough cleansing with a 1:1000 solution of bichlorid of mercury in water, although this step is not absolutely necessary and should not be advised to ignorant and careless individuals on account of the dangers from poisoning if bichlorid is swallowed; there is no danger, however, from the local application of such a solution, but stronger solutions are unnecessary and more likely to produce irritation.

(4) The parts are dried and about 1 dram of 33-per cent. calomel ointment well rubbed in, with particular attention to the glans, corona and prepuce, but neglecting no part of the penis, anterior portion of the scrotum and the pubis as well (aids in preventing pediculosis). At least ten minutes should be consumed in making the application and the parts should now be covered in order to protect the clothes, leaving the mercury to act, for at least twelve hours on any organisms that may remain.

As stated above, the base employed for preparing the calomel ointment does not appear to be as important as originally believed, and it is well to use Metchnikoff's formula:

Calomel	10 gm.
Lanolin	20 gm.

Anhydrous lanolin should not be used and it is important to have a *thorough mixture of the calomel and base.*

Other substances may be used but calomel is probably best. For example, Lenz[44] has recently advised a 0.3-per cent. (1:300) of bichlorid ointment. In experimental syphilis of rabbits I have had uniform success with applications of a tooth paste described in Chapter XXXI for the treatment of spirochetic and bacterial gingivitis, containing 1 per cent. arsphenamin and 0.5 per cent. mercurophen or bichlorid of mercury. An extensive series of experiments with syphilitic rabbits has convinced me that the application of this mixture is as efficacious as 33-per cent. calomel ointment, although it has the disadvantage of being yellowish in color and thereby more likely to stain the underclothing.

(5) For the prevention of gonorrhea, an intra-urethral injection of 10-per cent. argyrol may be given; recently, however, I have advised 10 per cent. neosilvol because it is colorless and does not have the objectionable brown discoloration of the former. In some prophylactic packets it is advised to inject a portion of the same ointment as is used for application to the external parts.

(6) At least two weeks must elapse with absolutely no signs of a discharge or sore before the individual may regard himself as having escaped gonococcus and chancroidal infections and at least six additional weeks must elapse without a sore before he may feel assured of having escaped syphilis, although the usual period of incubation is two to four weeks.

Method of Applying Genital Prophylaxis in Women.—As previously stated, prophylaxis among women is much more difficult and uncertain than among men and especially from the standpoint of vaginal and cervical infections; furthermore, a woman cannot ordinarily give herself an intraurethral injection for protection against gonorrhea.

Before coitus calomel ointment should be applied with special attention to the fourchet and a small amount introduced into the vagina. As soon as possible after coitus the parts should be thoroughly washed with soap and

water and a cleansing vaginal douche taken preferably of a quart of warm water to which has been added a teaspoonful of lysol. This should be followed by a douche of one quart of 1:2000 bichlorid solution, the individual being on her back, the nozzle well introduced and the solution held in contact with the cervix and vaginal walls for at least 5 minutes. After this the parts should be dried and calomel ointment thoroughly applied for ten minutes to the external parts, including the anus and pubis and particularly the labia minora and fourchet. A napkin should be worn for at least twelve hours before the parts are cleansed.

Since these measures may fail to prevent cervical infections, although very efficacious against infection of the external parts, it is well when connection has occurred with a man with a penile syphilitic lesion, to resort to abortive treatment in addition, which consists of several intravenous injections of neoarsphenamin, as described in the succeeding chapter.

Prophylaxis of Extragenital Syphilis.—Surgeons, obstetricians and midwives are especially exposed to the dangers of extragenital infections. I have seen several cases among surgeons after tonsillectomies upon syphilitics with open lesions in the mouth and fauces. I have never seen or heard of a case among pathologists due to necropsy inoculations; not among serologists as a result of drawing serum or blood from syphilitics into the mouth.

Needle-pricks and cuts should be encouraged to bleed, followed by immersion in hot 1:1000 bichlorid for at least ten minutes; after drying, 33-per cent. calomel ointment should be rubbed in for at least ten minutes and repeated every six hours for three applications, the excess ointment being left in contact for at least twenty-four hours. I believe these measures are sufficient, but if the chances of infection are great, it will be well to follow up with an intravenous injection of 0.6 gm. of neoarsphenamin every other day for two or three doses.

After exposure by kissing a syphilitic with a chancre on the lip or with mucous patches in the mouth, the lips, cheeks or other contaminated places should be washed as soon as possible with warm water and soap, dried and anointed for ten minutes with 33-per cent. calomel ointment, the excess being left on for at least twelve hours. The mouth may be rinsed out with 1:2000 solution of bichlorid several times, each mouthful being held for at least two minutes with due care against swallowing, the final washing being with water or dilute alcohol to remove the metallic taste.

CHAPTER LXXI

ABORTIVE TREATMENT OF SYPHILIS

As discussed in the preceeding chapter, it is possible to destroy *Sp. pallida* by various chemical substances including plenty of soap, if the applications are made within one to four hours after the parasites have gained access to the superficial tissues in either genital or extragenital contamination or infection; this is properly designated as *chemical or medicinal prophylaxis*. Not infrequently, however, prophylactic measures cannot be taken in time, are very imperfect or the individual does not know for one or more days that exposure to a syphilitic individual has taken place, all of these being especially true of women. If more than ten or twelve hours have elapsed and certainly if forty-eight hours have elapsed since exposure to open syphilitic lesions, it is highly probable that the application of 33 per cent. calomel ointment will prove ineffective for prophylaxis, since the spirochetes have in all probability multiplied to some extent, invaded the lymph spaces and even the neighboring lymphatics. At least, Brown and Pearce[1] have found that rabbits inoculated intratesticularly and scrotally may show the presence of spirochetes in the neighboring lymphatic glands forty-eight hours later and the same may occur in human beings. But there are no signs of infection beyond a possible abrasion and the primary sore or chancre does not appear for about ten days to two months, although the usual period of incubation is two to four weeks.

It is possible, however, to bring about a destruction of the spirochetes during this time and thereby prevent the development of the chancre and other lesions of syphilis; this may be properly designated as the *abortive treatment of syphilis* and constitutes the subject for consideration in this chapter.

The term is not infrequently employed, however, and especially by German writers, to designate the intensive treatment of syphilis during the primary or chancre stage, to abort the disease before secondary and later lesions appear; but in my opinion this is not the proper use of the phrase.

Abortive Treatment of Experimental Syphilis.—Curiously, but very little experimental work has been done on this important subject, although a number of clinical reports have appeared since 1919, when Taege[2] advocated the administration of three doses of sodium arsphenamin within a period of twenty-four hours for the abortive treatment of syphilis. Darier[3] reports that Dr. Magian of Paris experimented upon himself by inoculating his forearm from a primary lesion swarming with *Sp. pallida*, followed one hour later by the intravenous injection of 0.6 gram of arsphenamin. On subsequent observations over a period of 11 months no lesion appeared at the site of inoculation and the complement-fixation test remained persistently negative. Levaditi and Navarro-Martin[4] record a second human experiment in a young man, who 16 hours after inoculation, took by ingestion two grams of the sodium salt of oxy-aminophenyl arsenic acid; during a 47-day period of observation no lesions of syphilis developed.

The only reference to animal experiments which I have been able to find is that of Mibelli,[5] who states that Vecchia found that rabbits inoculated with syphilis do not develop the disease if neoarsphenamin in dose of 0.01 gram per kilo is given as late as 4 days after inoculation.

While it is impossible to duplicate exactly in rabbits the conditions pertaining to human infections, yet I believe they are of great importance in the study of this problem. With human volunteers there is always the possibility of latent unrecognized syphilis which may confer protection against superinfection with the result that failure to develop a lesion at the site of inoculation is ascribed to the curative activity of the drug administered; with rabbits this is easily avoided and numerous untreated controls may be included. Furthermore, with human beings treated after sexual exposure to syphilitics, the question of infection is assumed and cannot be proven; with rabbits the question of infection can always be definite and decided. With human beings the question of infection can only be decided by prolonged observation for the development of lesions and positive Wassermann reactions and it may be possible that primary lesions are not produced although infection of the lymphatics may occur; in rabbits the question can be decided by removing the regional lymph-glands and inoculating them into fresh animals. For these reasons, therefore, rabbit tests would appear to be of value in the study of this very important and practical subject.

During the past year, Greenbaum and Harkins[5a] made such a study in my laboratory. Rabbits were inoculated intratesticularly, as described in Chapter XXI, with a virulent strain of *Sp. pallida*, producing almost 100 per cent. positive infections in untreated controls. Ordinarily 0.010 gram of arsphenamin (disodium salt) produces the complete cure of such animals including sterilization of the lymph-glands, when the injection is given after a testicular lesion has developed (usually 3 to 6 weeks after inoculation); but this dose, which corresponds to 0.6 gram arsphenamin per 60 kilograms or 132 pounds, did not prevent the development of syphilis in rabbits when given three and twenty-four hours after inoculation. Even a dose three times larger, namely, 0.03 gram per kilo corresponding to 1.8 gram per 60 kilograms or 132 pounds, did not prevent syphilis when given three hours and twenty-four hours after inoculation. However, three daily doses of 0.010 gram per kilo were effective in that lesions did not develop and the lymph-glands were sterile.

Similar results were observed with neoarsphenamin. Ordinarily a dose of 0.015 gram of the best products given to rabbits with acute testicular lesions, results in their cure with sterilization of the lymph-glands. However, this dose, which corresponds to 0.9 gram per 60 kilograms or 132 pounds, given to rabbits three and twenty-four hours after inoculation did not prevent the development of lesions; even a dose three times larger, namely, 0.045 gram per kilo corresponding to 2.7 gram per 60 kilograms or 132 pounds, given three hours and twenty-four hours after inoculation failed to prevent the development of testicular lesions although three daily doses of 0.015 gram per kilo each were completely effective.

Sulpharsphenamin of the best grades is generally curative for rabbit testicular syphilis in dose of about 0.020 gram per kilo. Rabbits treated with a single dose of 0.015 gram per kilo, corresponding to 0.6 gram per 60 kilograms or 132 pounds, one and twenty-four hours after inoculation, developed testicular syphilis. Even doses three times larger, namely, 0.045 gram per kilo, corresponding to 2.7 gram per 60 kilograms or 132 pounds, failed to

prevent the development of testicular lesions when given one and twenty-four hours after inoculation. However, three daily doses of 0.015 gram each were effective.

These results were, therefore, very interesting and instructive. One would naturally suppose that smaller amounts of the organic arsenicals would suffice for the destruction of *Sp. pallida* given three to twenty-four hours after their injection into the tissues, than for the cure of well developed lesions containing thousands more of the parasites. But apparently such is not the case. If the inoculations had been given by abrasions of the scrotal skin, one may surmise that drugs introduced into the blood are eliminated too rapidly for them to reach parasites so superficially placed, but in Greenbaum and Harkin's tests the parasites were placed in the substance of the testicle. Naturally this raises the question of why arsphenamin, neoarsphenamin and sulpharsphenamin were found so much more effective in the cure of three to six weeks' developed testicular lesions than for three to twenty-four hour inoculations with little or no tissue changes. One may speculate at considerable length, since it brings up the question of the part played by the tissue reaction in defense and recovery from spirochetic infection. This subject has been already discussed in Chapter XXXVII, in which it is stated that the local tissue reactions, like the chancre, play a very important part in building up resistance to the progress of syphilitic infection and that anything preventing this reaction which fails at the same time to destroy all spirochetes, only hastens the multiplication and migration of the surviving organisms. The experiments have likewise shown the futility of single doses; at least three full-sized doses were required. I will, however, delay a further discussion of the subject in relation to the prophylaxis of human syphilis until the available literature has been reviewed; I hope it is apparent, however, that the subject is not as simple as one would at first suppose and furthermore, that it is of tremendous practical importance to individuals relying upon abortive treatment for escaping serious syphilitic infection.

Abortive Treatment of Human Syphilis.—As previously stated, Taege appears to have been first in advocating the abortive treatment of syphilis of human beings and in replying to Riecke,[6] who objected to the use of arsphenamin until the diagnosis of syphilis could be established, which he asserted was early enough done in the chancre stage of the disease to institute abortive treatment, states that the diagnosis of syphilis is not always possible early enough to adopt abortive treatment. He maintained that this was especially true in women, for whom the abortive treatment was peculiarly adapted.

Fournier and Guenot[7] report on the abortive treatment of syphilis by arsphenamin used during the incubation period. Forty women had been exposed to infection by sexual contact with syphilitics having genital lesions. The men were all examined, and the presence of *Sp. pallida* demonstrated by the dark field. The Wassermann reaction was positive in all except five, who had had the chancre less than ten days. The period since exposure for the women was from a few days to three weeks. The women were free of all suspicious lesions, the history did not lead to the suspicion of a previous infection, and the Wassermann reaction was negative in all. Not one had exercised any preventive measures. Five additional women, similarly exposed but who refused all treatment, were later attacked by syphilis.

The forty women were treated by injections of arsphenamin (a total of from 1 to 1.20 gm.), of neoarsphenamin (a total of from 1.2 to 2 gm.), or of an arsphenamin substitute. Not one of them ever showed any syphilitic lesions, and the Wassermann reactions of all have remained negative. Twenty of the women have been under observation over three years. One of the women, who after this treatment continued to receive her sexual partner, who had mucous patches for which he did not take treatment, contracted a chancre of the face.

Lacapere and Laurent[8] have reported the following four interesting observations on the abortive treatment of syphilis:

Of three officers who had intercourse with one woman who presented a pigmentary syphilis and numerous mucous patches of the mouth and vulva, two received a dose of neoarsphenamin (amount not mentioned) intravenously and remained unscathed. The third preferred to take his chances with infection and after the usual incubation period, presented the primary sore of syphilis.

The wife of an officer, who had connection with her despite his having a chancre and a positive Wassermann reaction, was given three injections of neoarsphenamin, in doses of 0.15, 0.3, and 0.45 gm., at intervals of six days. She never presented any lesions, and her Wassermann reaction remained persistently negative.

A young man with erosive syphilitic lesions of the glans and prepuce had repeated contacts each night for fifteen days with a young woman who presented no lesions, no history

of antecedent syphilis, and a negative Wassermann reaction. She was given eight injections (dosage not mentioned) of neoarsphenamin and she has remained free of lesions, and Wassermann negative.

A nursing heredosyphilitic infant had exposed two wet-nurses to infection. One of the two later nursed another infant. About eleven days after the last nursing of the first infant she presented a lesion of the nipple, from which spirochetes were demonstrated by the dark field. The child she was then nursing was certainly not a heredosyphilitic, and the possibility of infection was certain. At intervals of five days, neoarsphenamin, in doses of 10, 15, 20, 40 and 50 mg., was given intravenously. Eighty-five days after the last feeding from the affected breast, no lesions had appeared in the child.

Michel and Goodman state that they have used arsphenamin in the prophylaxis of syphilis while in the tropics, where a large proportion of the promiscuous women were affected with syphilis. At that time the use of the drug was limited to men who had been exposed over twelve hours and frequently as long as three days previously. These men were given three doses of arsphenamin, a total of 0.9 gm., within forty-eight hours. Other patients were treated with arsphenamin who had lesions typical of the so called soft sore or chancroid, in whom it was not possible to demonstrate spirochetes by dark field examination. This group was treated with the idea of preventing the appearance of manifestations of a syphilitic infection which was still in its first incubation period. Most of these men were under observation only for a period long enough to determine that there no chancres formed at the close of the ordinary period of incubation time of syphilis, or, in a few instances, as long as six months later.

More recently thirty patients have undergone the prophylactic treatment with arsphenamin. The patients that have been selected for this mode of abortive treatment have been, in the main, those in whom it was definitely possible to make a diagnosis of active syphilis in the opposing partner. This is a modification of the "diagnosis by confrontation" of the older writers in syphilis. For example, when the diagnosis of active syphilis was made those likely to have been exposed to infection, usually the wife, and less frequently the husband, were examined. In the instances reported, they have been found free of lesions, but the possibility that they were in the primary incubation period of syphilis was so strong that, rather than wait for the appearance of symptoms clinically or serologically, arsphenamin injections were instituted.

The prophylactic doses have averaged 0.3 gm. of arsphenamin, and the number and interval of the injections have varied with the time since first exposure. In no case has this been less than three doses. They have not been consistent as to the interval of injections, varying from an injection every other day to once in five days, depending on the general physical condition of the patient. The women have been awarded the longer interval in the great majority of the cases. The patients treated in this manner have been under observation long enough to state that the primary incubation time passed without the appearance of primary lesions. No patient treated in this manner has developed a positive Wassermann reaction, although it was not possible to repeat the tests in every patient.

At the fifth Congress of the Northern Dermatological Society held in Stockholm in 1922, Heden[10] reported on 36 individuals who had had intercourse with syphilitics presenting open lesions and who had taken abortive treatment. Twenty of these cases had received neoarsphenamin and none developed lesions of syphilis over periods of observation ranging from 1½ months to 8½ years; all had been exposed 2 to 13 days (one case 3 weeks) before the injections were given. All escaped syphilis while of 36 additional control cases to whom abortive treatment was not given, 30 developed syphilis.

Hecht[11] reports on five cases, wives of men recently infected with syphilis, who were given abortive neoarsphenamin treatment (in dosage of 1.35 gm. in 10 days), and none of whom apparently developed syphilis. May[12] reports that prompt abortive treatment prevented the systematization of syphilis in two physicians, one whose eye was infected with syphilitic saliva and the other who cut his finger in puncturing a chancre. Favorable reports have also been made by Nicolan,[13] Golay,[14] Schmitzer,[15] Mibelli,[16] Gouin[17] and Rostenberg.[18] Simon[19] states that abortive treatment should only be given within 72 hours of exposure and not after this time for fear of only preventing the development of a chancre and giving a false sense of security. He advises at least three injections of neoarsphenamin in dose of 0.3 gm. every three days with a Wassermann test two weeks after the last dose and then monthly for at least four months. Schonfield[20] has suggested it as possibly worth while for prostitutes to receive a monthly injection of arsphenamin or neoarsphenamin for abortive treatment. Sutton[21] believes that when there is exposure to syphilis, even when the evidence of infection is presumptive, as in rape or when prophylaxis is neglected or delayed, abortive treatment consisting of injections of from 0.2 to 0.4 gm. of neoarsphenamin are worth while. He states that this has been apparently successful in two cases, one when a needle contaminated with the blood of a syphilitic was accidentally jabbed into a surgeon's forearm, and once when an assistant's eye and cheek were splashed

with blood; also in several additional cases when the hands were exposed in the handling of chancres and during operations on syphilitic patients. Martinotti,[22] however, is opposed to abortive treatment immediately after exposure, believing that it is better to wait for the development of the chancre and then to resort to intensive treatment.

Levaditi, Fournier and other French authors have reported the successful abortive treatment of syphilis in rabbits and man by the administration of stovarsol by mouth. This drug is given in dose of 4 tablets (0.25 gm. each) every morning before breakfast in a little water for 5 to 7 days; after intervals of 5 to 7 days the treatment is repeated so that the patients receive about 12 to 16 grams during the first month. In two men the development of syphilis is said to have been prevented, in spite of massive inoculation with spirochetes, by this drug. The number of persons who have been protected from infection by the drug in spite of sexual contact with a partner with florid syphilis is said to be considerable, but as stated by Bloch[23] and others the remedy is not a harmless one, is no more free from unpleasant or even injurious by-effects than its predecessors and the results are not yet sufficiently conclusive for using the drug in general practice.

Limitations and Practical Value of Abortive Treatment of Human Syphilis.—But it would appear that abortive treatment of human syphilis has been proven possible and to possess practical value under the following conditions:

(1) For individuals of either sex exposed sexually or extragenitally to active, open cases of syphilis when the prophylaxis described in the preceding chapter has not been applied within four hours of exposure or when improperly applied. If the prophylactic has not been applied at all or after four hours, the abortive treatment is indicated when it is practically certain that the sexual partner has acute open lesions of syphilis.

(2) Exposure of either sex to chronic, latent cases of syphilis with no open lesions, in whom the only evidence of syphilis may be a positive Wassermann reaction, does not call for abortive treatment even though prophylaxis has not been practiced. Under these conditions the chances of infection are so much less that I believe it is far better for the individual to take his or her chances and have the matter definitely settled by watching for the appearance of lesions to be followed by immediate, intensive treatment if such develop.

(3) The value of prophylaxis according to the method described in the preceding chapter has been more firmly established when properly applied within four hours after exposure, than has abortive treatment.

(4) Abortive treatment may be given any time from twenty-four hours to two weeks after exposure. But if more than two weeks have elapsed I believe it is better to wait for another week or two for the appearance of a chancre in order to settle the question, preparations being made to institute intensive treatment upon the first positive signs of syphilitic infection.

(5) The Wassermann reaction is of no value for detecting infection during this primary stage of syphilis. If it is done and is found positive, the individual is probably already syphilitic and almost surely will not develop a chancre even though repeatedly exposed. He is, however, a fit subject for antisyphilitic treatment.

Method of Abortive Treatment for Human Syphilis.—If abortive treatment is to be given, the results of animal experiments and clinical experience teach that it must be thorough to be worth while. Doubtless some cases may be cured by a single injection of arsphenamin or neoarsphenamin, a true example of Ehrlich's *therapia sterilisans magna*, but this is risky and not to be recommended even though treatment is given within twenty-four hours after exposure. Furthermore the administration of mercury and bismuth should not be considered at all; the best one may do is to administer the most active spirocheticides as arsphenamin, neoarsphenamin or sulpharsphenamin with particular care to chose the best brands of the latter on account of their variability in parasiticidal effects.

The doses and number of injections to be given vary according to the time elapsing since exposure; in my practice the following plan is employed:

(1) When exposure has been within three days: Two doses of arsphenamin (0.4 to 0.6 gm. each) at intervals of three days; or three doses of neoarsphenamin (0.6 to 0.9 gm. each) at intervals of three days; or three doses of sulpharsphenamin (0.4 gm. each) at intervals of three days.

(2) When exposure has been within four to seven days: Three doses of arsphenamin (0.4 to 0.6 gm. each) at intervals of four or five days; or four doses of neoarsphenamin (0.6 to 0.9 gm. each) at intervals of three to four days; or four doses of sulpharsphenamin (0.4 gm. each) at the same intervals.

(3) When exposure has been within eight to fourteen days: Four doses of arsphenamin (0.4 to 0.6 gm. each) at intervals of five days; or six doses of neoarsphenamin (0.6 to 0.9 gm. each) at intervals of three to four days; or six doses of sulpharsphenamin (0.4 gm. each).

(4) For periods longer than fourteen days I believe abortive treatment is inadvisable but if insisted upon, I recommend the same treatment as advised in the succeeding chapter for Wassermann negative cases of primary syphilis.

(5) The patient is kept under close observation with periodical thorough examinations of the parts and lymphatic system for at least three months. The Wassermann test may be done if expense is no particular consideration, but the reactions are usually negative since the Wassermann antibody or "reagin" is not produced in sufficient amounts for detection until the spirochetes have proliferated to the extent of producing tissue changes.

CHAPTER LXXII

SPECIFIC TREATMENT OF EARLY SYPHILIS (PRIMARY AND SECONDARY STAGES)

Necessity for Early Diagnosis in Relation to Specific Treatment.—Since it is now easily possible in the majority of cases to establish the exact nature of the primary sore of syphilis by microscopical examination of the secretions for *Sp. pallida* and especially by the dark-field method, it is not necessary to follow the old custom of permitting the disease to progress to the stage of the cutaneous and mucous membrane eruptions (secondaries) before the diagnosis is made and treatment instituted. The Wassermann test is not of much value at this time, because the chancre must be present for about ten days before sufficient "reagin" or "Wassermann antibody" has been produced in the blood to give a positive reaction; indeed, a special effort should be made to establish the diagnosis and institute treatment before the Wassermann reaction becomes positive and to prevent it from ever becoming positive. As stated in Chapter XXXIX, the Wassermann test conducted with chancre secretions may yield a positive reaction, but as a general rule the dark-field microscopical examination is a better means for early diagnosis.

A large and constantly increasing experience and literature from all parts of the world testifies to the fact that the earlier treatment is instituted, the better are the chances for complete recovery; it is not improbable that many paretics and tabetics owe their condition to a failure of diagnosis on account of a small and atypical chancre and poorly-developed and evanescent secondaries which resulted in a failure of clinical diagnosis of syphilis and the institution of vigorous treatment during the early stages when most was possible from the therapeutic standpoint. It is true that as the disease is allowed to progress untreated, certain immunological changes occur in the chancre and each succeeding lesion tending to hinder progressive involvement of organs, but, as stated in Chapter XXXVII, the value and importance of these in relation to complete recovery from syphilis must not be over-rated and there is little or no evidence to indicate that human beings completely recover from syphilis unaided by specific medication. In other words, we are not justified in delaying the institution of specific medication in early syphilis simply to acquire the benefit of these immunological changes; our duty is to establish the diagnosis as soon as possible and to institute appropriate specific treatment without delay.

Classification of the Lesions of Early Syphilis in Relation to Specific Treatment.—As a general rule, the *chancre* or primary syphilitic lesion develops in two to four weeks after infection. The duration of this period of *primary incubation* varies according to the virulence of the infecting spirochetes, the numbers inoculated and the degree of tissue injury; but reported instances of incubation periods as brief as ten days and even one or two days are probably in error, infection having occurred at an earlier date than ascertained. Within a few days after the appearance of the chancre, the spirochetes have already invaded the lymphatic channels and neighboring lymphatic glands. No other changes may be apparent except the chancre, adenopathy and a peculiar characteristic pallor or anemia.

This constitutes the primary stage of syphilis according to Ricord's classification. As previously stated the Wassermann test does not usually yield a positive reaction earlier than ten to twelve days after the first appearance of the chancre and autoinoculability of the chancre usually terminates by the twelfth day; this period is designated by some German writers as the *prehumoral stage.* I do not like the term, however, because so much evidence indicates that spirochetes may be in the "humors" (blood and lymph) at this time and it is highly probable that minute amounts of the complement-fixing "reagin" or "Wassermann antibody" are likewise present, since Klauder and I have found it in the chancre secretions; we may not detect it in the blood simply because our methods are not sufficiently sensitive. However, from the standpoint of specific treatment it is serviceable to divide the chancre or primary stage into the *Wassermann negative* phase, during which autoinoculation is possible and may occur and the *Wassermann positive* phase, subsequent to which autoinoculation does not occur. As stated above a special effort should be made to establish the diagnosis and institute specific treatment in the former phase.

In the absence of treatment, the chancre slowly disappears and usually within six to seven weeks after its appearance, the skin and mucous membrane lesions appear associated with generalized adenopathy, the falling out of the hair, anemia and various symptoms constituting the *secondary stage* according to Ricord. In exceptional instances it is claimed that these lesions may develop any time within two years after the appearance of the chancre, but, from the standpoint of relation to specific treatment, I believe that the secondary stage of syphilis is to be classed with acute, early syphilis only when these lesions present themselves within two to four months after the appearance of the chancre; after this time the disease has actually entered upon its chronic stages since sufficient time has elapsed for fibrosis of capillaries and the early organization of lesions and the eradication of spirochetes becomes much more difficult with the demand for much more specific medication over longer periods of time. In other words, the acute skin and mucous lesions sometimes developing one or more years after the chancre are not secondaries in the usual meaning of the term, but simply acute exacerbation of chronic syphilis in which large numbers of spirochetes have been suddenly distributed to the skin with the production of similar lesions. The treatment of such, however, is essentially the problem of treatment of the underlying chronic lesions wherever they may be situated.

Acute, early syphilis therefore in my opinion, covers the first three or four months of the disease from the first appearance of the chancre or about five to six months from the approximate time of infection; when the disease is present for longer periods, I believe it is proper to designate it as "chronic" both from the standpoint of pathological tissue changes and specific therapy, even though the lesions may be so small or so situated as to fail to produce symptoms during the ensuing so called period of *latency or secondary incubation,* which is of variable duration, before detectable lesions and symptoms of the *tertiary stage* develop.

Advice to the Patient.—It is imperative for the physician to explain carefully to the patient the nature of the disease, its seriousness, its infectiousness and the necessity for guarding against spreading the disease and for thorough and prolonged treatment; also such directions as to diet, the use of alcohol and tobacco, the care of the mouth and general hygiene covered in Chapter LXIX.

It is quite common to find among the laity an exaggerated opinion of the curative activity of a few "shots" of "606." It is true that the adminis-

tration of arsphenamin or one of its substitutes removes the spirochetes from the open lesions much more rapidly than in the pre-salvarsan days, but the necessity for prolonged treatment and observation is scarcely less now than formerly; while I am opposed to gloomy prognoses and any statement tending unduly to frighten the patient, yet I believe it is well for the physician at the outset to impress upon the patient the fact that there is no real "short cut" to cure and that while complete cure is both quite possible and probable, it will be the reward only of careful and persistent effort and coöperation on the part of patient and physician. The responsibility of explaining the infectiousness of the disease and its danger to others by direct contact or parental transmission, as well as the necessity for treatment even after the obvious lesions have been dissipated, is especially onerous in public clinics, because so many of the poorly educated, and particularly colored men and women, are difficult to convince that treatment may be required even after lesions have disappeared and they are feeling and appearing in apparent good health. Printed slips are frequently useful for giving the necessary information and some scheme of this kind is always advisable when it is impossible for the physician to devote a sufficient amount of his own time and efforts in this very important part of the treatment of acute, early cases of syphilis.

Situation of the Chancre in Relation to Treatment.—Ordinarily, the situation of the chancre has no direct bearing upon specific treatment; that is, a chancre of the lip, for example, receives the same treatment as one on the genital organs. This is true, however, only when fairly intensive methods of specific therapy are employed; otherwise distinctions should be made. For example, the progress of a chancre of the lip should be promptly checked to prevent scarring as much as possible; furthermore, owing to rich vascular and lymphatic channels, systemic dissemination of spirochetes is probably greater than occurs in genital chancres. Wherever chancres are so located that ulceration may result in deformity or interference with functions, energetic specific therapy should be instituted as quickly as possible; while some syphilologists have stated that extragenital chancres are more refractory and systemic infection more likely than in the case of genital chancres, this has not been my own experience. I have seen chancres of the fingers, lip, tonsils, eye-lids, nasal mucosa, forehead, etc., yield as promptly and satisfactorily to specific medication as chancres of the genital organs.

Local Treatment of the Chancre.—This subject has received a great deal of attention and discussion in former years when it was commonly believed that syphilis was purely a localized infection during the primary or chancre stage. Hunter, Ricord and even more modern syphilologists have been warm advocates of excision or cauterization of the chancre with the idea that such measures effectually removed the disease. Circumcision and cauterization are still practiced for this purpose and not infrequently we meet with chronic cases of syphilis to-day among patients who were assured by their physicians that cauterization of the sore with carbolic acid, silver nitrate, etc., had removed all danger. Such measures applied to non-syphilitic lesions as herpes, chancroids or simple abrasions mistaken for syphilis, may readily enough lead both physician and patient into the mistaken conclusion that local treatment resulted in a complete cure and removal of syphilitic infection, but there is now available overwhelming clinical and experimental data showing that circumcision and cauterization of a true syphilitic chancre rarely succeeds in removing all infection and subsequent generalization of the disease.

Histological examination of excised penile chancres shows that the lymphatic spaces are invaded by spirochetes and lymphocytes for an area of

almost an inch or more beyond the lesion, even though these changes are detectable only by microscopical examination; it may be that a chancre located on the tip of a long foreskin and excised during the first day or two with a wide sweep of apparently uninfected tissue may be effective, but these are certainly exceptional and even rare circumstances. Furthermore it would appear that spirochetes may be present in the inguinal glands within a few days after the chancre appears; even fifty years ago this fact was appreciated and some went so far as to advise injections of mercury to block off the lymphatics between the chancre and the glands and even to excise the latter, but in view of the large number of lymphatics and glands and since the glands in both groins are involved, these suggestions now appear foolish and only of historical interest.

If, however, a chancre occurs on a foreskin long enough to produce phimosis, therefore rendering circumcision advisable for general reasons, or upon the labia minora, rendering easy the matter of excision, the operation of removal may be conducted and is frequently recommended by modern syphilologists, but never with the advice to the patient that the operation removes the disease, since the incidence of failures has far exceeded the apparent successes; at least, an enormous number of spirochetes are removed *en bloc*, but another chancre may develop in the scar and an important depot for antibody production is removed, rendering very hazardous any dependence alone upon excision for the cure of syphilis. Indeed, this is so true that the excision of a true syphilitic sore (chancre) should always be followed by thorough and vigorous specific medication, since it is entirely likely that the spirochetes escaping removal will now be able to proliferate and migrate even more vigorously and extensively than would otherwise be the case.

If circumcision, therefore, is so likely to fail that it occupies no place in the treatment of syphilis insofar as dependence is to be placed upon it alone for eradication of the infection, how much more likely is cauterization to fail! And yet not a few physicians and the laity believe in its efficacy. A host of substances have been advocated and especially phenol followed by alcohol, sulphuric acid, fuming nitric acid, silver nitrate, copper sulphate, the actual cautery, etc. All of these produce immediate coagulation necrosis of the tissues and, while it is freely admitted that those spirochetes directly reached may be destroyed, how about those which may not be reached in the deeper portions of the chancre and in the margin of the lesion? It is foolish to even expect their destruction by such means, not to mention the pain produced and resulting necrosis which may become secondarily infected with pyogenic bacteria with the production of phagedenic ulcers and suppurative adenitis. Circumcision may actually accomplish something worth while when followed by adequate specific treatment; there is nothing to be said in favor of cauterization of the chancre insofar as the cure of syphilis is concerned. Sometimes, however, the chancre requires vigorous local treatment and especially if phagedenic; for this purpose the treatment proposed by Bausbach[1] is to be recommended, consisting of calomel 10 parts, zinc sulphate 10 parts, and chlorin water 50 parts applied on a piece of cotton, covered with oiled silk, and left in place for twenty-four hours.

As a general rule, the chancre should be merely treated with wet dressings of saline solution until the diagnosis has been made preferably by microscopical examination of the secretions for *Sp. pallida* and especially by the dark-field method. Dressings of this kind are usually sufficient for promoting drainage, particularly if hypertonic saline (10-per cent.) is employed, and for keeping the sore free of excessive suppuration. After the diagnosis has been established the sore may be treated with 1:1000 bichlorid of mercury

preferably in 10-per cent. saline solution, boric acid solutions, 33-per cent. calomel ointment or by dusting powders of calomel, aristol, etc. The wet dressings, however, are preferred when there is considerable mixed infection and suppuration with adenitis, because they do not hinder absorption of the pus into the dressings as may an ointment or the heavy application of a dusting powder. As a general rule, I prescribe the bichlorid dressing for the first week, followed by the ointment and lastly by a dusting powder until the sore has completely healed. A dusting powder of arsphenamin may be employed, but it is more expensive, is apt to discolor the underclothing and is probably not any more spirocheticidal than calomel.

Choice of Drugs for the Specific Treatment of Primary and Secondary Syphilis.—Since the indications are for the destruction of spirochetes as rapidly and thoroughly as possible, practically all syphilologists at the present time are agreed that arsphenamin, neoarsphenamin or sulpharsphenamin are the remedies of choice; when for any reason these drugs cannot be given, probably bismuth ranks next and mercury third. The iodids are so feeble in spirocheticidal activity that they are not to be considered at all as primary remedies in acute, early syphilis, although they may be given later with advantage. The soluble and insoluble salts of mercury in ordinary doses are almost without effect upon the spirochetes in the chancre and mucous patches although these lesions gradually heal under mercurialization; even large doses approaching toxic effects influence the spirochetes much less promptly than arsphenamin and its substitutes, as shown by Scholtz and Kelch,[2] Ineyrat[3] and others.

However, mercury still has a definite place in the treatment of acute, early syphilis. While there are numerous cases on record of apparent cures from arsphenamin or neoarsphenamin alone, yet to-day there is a growing tendency in favor of mixed treatment and my own practice is to administer courses of mercury after arsphenamin or one of its substitutes. This is primarily as a safeguard for the destruction of those parasites entrenched in the lymphatic glands or other tissues and escaping arsenical destruction.

The matter of choice of arsenical is largely one of individual opinion. Since 1918 neoarsphenamin has become undoubtedly more popular than arsphenamin, largely because of its greater ease of administration and greater freedom from toxic reactions permitting more intensive treatment than is usually possible with arsphenamin. I believe that neoarsphenamin is to be preferred for these reasons, but only when a neoarsphenamin of superior parasiticidal properties is employed. As I have discussed with more detail in Chapter LXVII, to use neoarsphenamin merely on the basis of greater ease of administration and low toxicity for rats is a mistake; it is true that most all compounds including the much less spirocheticidal pentavalent compounds, produce healing of the lesions as this is not a difficult task, but when reliance is placed upon neoarsphenamin in this critical period of therapeutic opportunity, due care must be taken to build with a foundation of rock rather than with one of shifting sands. With arsphenamin there is much less opportunity for an error of this kind; undoubtedly it is the remedy of choice at this stage of the disease when the best spirocheticidal effects are desired because it is the most uniform and active spirocheticidal agent available at the present time.

Tzanck and Dohen[4] have employed sulfarsenol by subcutaneous injection but on account of numerous failures have expressed a preference for large doses of neoarsphenamin by intravenous injection; Stokes and Behn,[1] however, have recently stated that intramuscular injections of an American brand of sulpharsphenamin have yielded them as good clinical and serological

results (92.8 per cent. cures) in primary and secondary syphilis as in patients treated previously in a similar manner with arsphenamin (94 per cent. cures). Certainly when intravenous injections of arsphenamin and neoarsphenamin cannot be given, intramuscular injections of sulpharsphenamin should be resorted to, the method employed by Stokes and Behn being given later in this chapter.

In reference to the choice of a mercurial compound, I believe that inunctions are to be preferred when it is possible to apply them in a thorough and acceptable manner; otherwise, intramuscular injections should be given, my preference being for the succinimid in almond oil with the salicylate in oil as second choice. When, however, it is necessary to rely mostly upon mercury for the treatment of those exceptional cases of hypersensitiveness to arsenic, I believe that intravenous injections of flumerin or mercurosal are first choice for a short series of administrations followed by intramuscular injections of the succinimid; mercury by ingestion should never be resorted to for the treatment of primary and secondary syphilis when the most prompt spirocheticidal effects are indicated and desired.

Influence of Specific Medication upon Immunity in Early Syphilis and the Dissemination of Infection, Especially in Relation to Neurosyphilis.—Does arsphenamin and its substitutes employed in the treatment of early syphilis increase the incidence of neurosyphilis? There are some physicians who believe that the incidence of neurosyphilis, cardiovascular syphilis and chronic syphilitic infections of other organs has increased since the advent of salvarsan and that the onset of neurosyphilis has been precipitated or hastened in some cases by the use of this drug. Probably this impression is due in part to our improved methods for the clinical and serological diagnosis of syphilis and especially of neurosyphilis by examinaton of the cerebrospinal fluid, but aside from this it is pertinent and important to examine the question in an unbiased manner.

As explained in Chapter XXXVII, it has been quite definitely proven that when early syphilis is left alone and untreated, the tissues are capable of setting up some immunological mechanism of cellular resistance to the parasites and some physicians believe that in early syphilis we may do well to revert back to the practice of older syphilologists in delaying treatment until the secondaries appear, not so much to clinch the diagnosis as was their purpose, but to give the body sufficient time to muster or mobilize its cellular resistance. Now this cellular resistance is stimulated only by living spirochetes; vaccines of dead spirochetes unfortunately do not aid, as explained in Chapter XXIII. The only way to obtain it at present is by leaving sufficient living spirochetes in the tissues. If we reduce their numbers by sub-sterilizing doses of spirocheticides, the results of animal experiments have shown that the survivors meet with less resistance, are more quickly disseminated and more quickly produce infections of distant organs. It is conceivable that the specific treatment of early human syphilis may have the same effects and similar results and that our best spirocheticides, like arsphenamin and its substitutes, may actually spread the parasites in the body if given in amounts only sufficient for dissipating the chancre and adenopathy but short of complete sterilization. On the other hand, if we leave the cases untreated dissemination will occur anyhow, although not so rapidly, and there is practically no hope that cellular resistance alone will extirpate the infection or hold the disease in indefinite latency. So there we are—we must make our choice.

What should we do? Deliberately wait until the organisms are widely disseminated and the secondaries produced before treatment is instituted in order to obtain the maximum degrees of cellular resistance and especially

from the skin, which organ is apparently particularly active in this regard? Or treat with mercury by ingestion or injection after Fournier's plan which served to hasten the healing of the chancre and to mitigate the secondaries but probably leaving enough surviving spirochetes to stimulate cellular resistance? Or try to obtain similar results with small doses of arsphenamin and its substitutes which however is much more difficult to accomplish because if the dose is too small the spirochetes may be actually stimulated? Or should we endeavor to affect a radical cure by the prompt and vigorous administration of arsphenamin and its substitutes realizing that we may occasionally fail but that success is apparently in reach in the majority of cases because the vital organs are in such good general condition that we need not greatly fear dangerous toxic or organotropic effects?

The last is my choice for the treatment of the majority of cases of early syphilis in good general condition, because present results indicate that the incidence of chronic syphilis developing among intensively treated early cases is less than 5 per cent. I realize, however, that common sense must be exercised in dosage. Too much arsphenamin or neoarsphenamin may do harm if toxic tissue changes and capillary injuries are produced. I believe that it is possible to effect radical cures, however, without discernible damage; at least, the damages are apparently rapidly healed. On the other hand, I believe it is to be admitted that insufficient arsenical therapy may actually do harm in the way of depressing cellular resistance by sub-spirocheticidal effects, enabling surviving organisms to produce early lesions in the central nervous system and other distant organs. Since the general practice is to give too little arsphenamin and neoarsphenamin, usually enough to dissipate the lesions but short of complete sterilization, it may be indeed true that the incidence of neurosyphilis has actually increased during the past fifteen years. I believe that the old fashioned chronic intermittent mercury treatment is to be preferred to a few desultory injections of arsphenamin or neoarsphenamin, but that best results are secured by bold and thorough arsenical treatment within common sense limits; the latter is my practice and the method of application shortly follows.

Dosage and Intervals of Administration of Arsphenamin and Its Substitutes in the Treatment of Primary and Secondary Syphilis.—One of the results of the discovery of arsphenamin and neoarsphenamin was to foster the long cherished hope for a standardized method for the treatment of syphilis, at least for early syphilis in the primary and secondary stages of the disease. The dose to employ, the number of injections to be given, the intervals between injections, the number of injections constituting a course and the number of courses to be given have ever been perplexing subjects calling forth a voluminous literature detailing various methods and plans. If we had a sure and applicable method for determining when a syphilitic is really cured in the sense of complete eradication of all spirochetes, analogous, for instance, to the gland transplants of rabbits, the problem would be much easier to solve; but in human syphilis we can rely only upon the dissipation of obvious lesions, negative complement fixation reactions with blood serum, negative results of cerebrospinal fluid examinations and, lastly, but most important of all, upon the final clinical records of individual patients during the balance of their lives. We do not know therefore in accurate terms, what may be the real value and what will be the final outcome, of our modern plans of treatment. At present we must rely upon rigid clinical examinations and especially for neuro-recurrences, repeated blood complement-fixation tests with the most sensitive but specific methods and examinations of spinal fluid, as our guides and criteria while waiting for Time to close

the chapter. It is extremely difficult to evaluate present day methods of treatment because of wide variations in the clinical skill and judgment of those reporting their results and especially because of a deplorable lack of sensitiveness and accuracy of serological tests upon which opinions are based.

How can the radical or complete cure of syphilis in the primary and secondary stages be best attained? We must seek for our answer in the clinical experiences of others and ourselves employing different preparations, varying doses and varying plans of administration; also from the results of carefully planned therapeutic experiments with the lower animals infected with syphilis and finally base an opinion upon these with the reservation that it may require revision in the light of future experience as we are able to follow our patients through the balance of their lives.

Keeping in mind the main facts concerning the rates of absorption and elimination of arsphenamin and its substitutes, the probable mechanism of their spirocheticidal activity, toxicity for body cells and ultimate fate as discussed in previous chapters, what constitutes the best plan for their administration? Is a large dose at long intervals, say seven days' as good or better than a large dose at close intervals? Is a small dose at close intervals as good or superior? How much must be the total administered by either plan for radical effects? As pointed out by Hatcher and Wilbur,[6] the intensity of the action of a given drug usually depends largely on the total amount that acts at one time, and this is determined to some extent by the ratio between the rate of absorption, on the one hand, and that of elimination or destruction in the body, on the other. A large dose of a drug may produce less effect at one time than a small dose administered in the same way at another time, the difference in the intensity of action being due to differences in the rates of absorption and elimination. It is not equally well understood, however, that low concentrations of a chemical compound may affect protoplasm in a distinctly opposite manner from that provoked by larger proportions; for example, a very small dose of arsphenamin or neoarsphenamin may actually prove dangerous from the standpoint of stimulating the multiplication and activities of spirochetes instead of destroying them, as shown by Bronfenbrenner and Schlesinger[7] in the treatment of syphilitic rabbits. Brock[8] states that doses of 0.03 to 0.04 gm. of arsphenamin for adults neither cures nor favorably influences acute early syphilis; Balzer,[9] on the other hand, states that the daily subcutaneous injection of sulfarsenol in dose of 0.010 to 0.030 gm. until a total of 4 to 5 gm. has been given yields excellent results. Scholtz and Kelch[10] state that a total of 0.2 gm. of arsphenamin divided into two doses a day of 0.05 gm. each for two days followed by two doses of 0.25 gm. on the third day and one dose of 0.3 gm. on the fourth day is the most effective method for bringing about a rapid disappearance of spirochetes from chancres.

A great deal of attention is being given at present to intensive treatment, improperly designated as "abortive treatment" by German and French authors. Pollitzer[11] in America and according to Artz,[12] Notthaff in Germany, have been pioneers in the method of "striking hard" by short intensive courses comprising three or more daily injections of 0.4 to 0.6 gm. of arsphenamin. Ineyrat and Pinard[13] have likewise subscribed to this plan beginning with 0.15 gm. of arsphenamin and reaching 0.6 gm. by the eighth injection. Katz[14] claimed many years ago that 0.3 gm. of arsphenamin as a dose was just as effective as the 0.6 gm. dose recommended by Ehrlich, and Hazen,[15] Ormsky,[16] Ballenger and Elder,[17] Goodman,[18] Gennerich,[19] Oliver,[20] Polland[21] and others, while advocates of intensive treatment are in favor of

small doses of arsphenamin (0.2 to 0.4 gm.) or neoarsphenamin (0.4 to 0.5 gm.) rather than the maximum doses of 0.6 gm. and 0.9 gm. respectively.

Pollitzer has advocated at least three daily doses of arsphenamin, but many others have found this plan inadvisable if toxic reactions are produced. I have likewise abandoned it when toxic reactions are produced, although it is usually possible to give three daily doses of 0.3 gm. arsphenamin (disodium salt) in 30 c.c. by syringe injection without untoward effects; within the last few years I have used neoarsphenamin in three to six daily doses in amounts of 0.6 gm. each with apparently equally good therapeutic results and remarkable freedom from untoward effects. The majority of syphilographers, however, have been more in favor of longer intervals between injections, as two per week of neoarsphenamin and one of arsphenamin every 5 to 7 days.

Whatever may be the dose and interval of injection employed, it would appear that most writers claim that at least a total of 4 to 5 grams of arsphenamin or neoarsphenamin are required for the cure of primary and secondary cases of syphilis. The old idea of Ehrlich of curing the disease with a single injection of 0.6 gm. of arsphenamin was soon disproven even in the treatment of the earliest chancres, although this dose may bring about the prompt disappearance of the spirochetes from the lesion followed by prompt healing. Biele[22] mentions a woman who received 3 gm. of neoarsphenamin in one injection in mistake for 0.3 gm. Her Wassermann reaction became negative without further treatment five weeks later although the patient had had a previous injection of 0.45 gm. of neoarsphenamin and some mercury. It is interesting to note that only slight toxic symptoms followed the large single dose; these disappeared within five days after injection.

Various Methods Proposed for the Treatment of Primary and Secondary Syphilis.—As previously stated, a very large number of plans and methods for the treatment of primary and secondary syphilis have been described in the literature and Baketel[23] has recently published many more from personal correspondence with American syphilologists some of which I am quoting below from his article; space does not permit me to present all of these, but some are given herewith as examples to show the trend of thought and practice in the search for a standard method:

Fordyce and Rosen, of New York, treat cases with positive dark-field and negative Wassermann reactions with 8 intravenous injections of arsphenamin in dose of 0.3 to 0.5 grams, the first three every other day, and the remaining five, every five to seven days. The second course of six injections is given after an interval of four to six weeks. Patients who have never developed positive serologic findings are considered as aborted cases and are under observation for at least a year, with monthly blood tests. If a positive Wassermann reaction develops during treatment, the patient is given the same treatment as the early secondary cases, namely, three injections of arsphenamin, one every other day of 0.3, 0.5 and 0.6 gms., and the remainder every five to seven days until eight injections have been given. Mercury is given during this course consisting of 15 intramuscular injections of salicylate, grs. 1 to 1.5, every seven days or, if soluble mercury is employed, bichloridol, gr. 1, every four or five days. Notwithstanding a possible negative result, the treatment is repeated after the patient has had a four to six weeks' rest, being given eight more weekly injections of arsphenamin and 15 of mercury. If necessary, the patient is given a third course of the same number of treatments after the usual period of rest. Should the Wassermann test be negative, a rest of three months is advised followed by a course of 6 arsenic and 10 mercury injections.

Schamberg, of Philadelphia, advises that in the treatment of primary syphilis in an individual in average good health and of normal weight, two doses of 0.9 gm. neoarsphenamin may be given each week for two to three weeks, followed by weekly injections until ten administrations in all have been given. This is provided the drug is well tolerated. After this, a course of mercurial injections or inunctions are given. At the end of this period if the Wassermann reaction is negative, the remainder of the treatment may be mercurial. Mercurial pills may be given over a period of some months to insure cure.

This treatment represents in a way a combination of the new with the old treatment of syphilis. In the event of a positive Wassermann, neoarsphenamin is again administered every week for twelve injections and again followed by mercurial injections or inunctions.

The treatment of secondary syphilis is largely that of primary syphilis save that more courses of treatment are given, independent of the outcome of the Wassermann test. In other words, there is an irreducible minimum of treatment. Three courses of 8 to 10 injections of the arsenical employed, with three courses of mercurial injections or inunctions constitutes such a minimum in his opinion. A negative Wassermann reaction after a brief course of treatment is by no means regarded as an indication of the death of all of the spirochetes in the body. His experience demonstrates that lapse of treatment at such times is commonly followed by a recrudescence of a positive reaction. No definite rule is set down as to the number of treatments which any given patient may require. After a negative Wassermann reaction, mercurial treatment by month is continued for long periods.

Moore, of Baltimore, begins the treatment of early syphilis with arsphenamin, the first course being of eight doses and succeeding courses of six doses each. Mercury by inunction is started just before the last dose of each arsphenamin course, and continued until the first dose of the next. The interval between arsphenamin courses is at first short (four weeks), and is gradually lengthened with each course. The longest interval permitted is twelve weeks. Spinal puncture is performed as a routine after the first or second course of arsphenamin. The treatment of Wassermann negative primary syphilis usually lasts exactly one year, and consists of at least four courses (26 doses) of arsphenamin and twenty-six weeks of mercury. In Wassermann positive primary and in secondary syphilis, the length of treatment in the average case is usually 15 months (five courses of arsphenamin and thirty-two weeks of mercury). If spinal fluid abnormalities are found at the time of the first puncture, this plan is modified according to the findings. When treatment has been completed, there ensues a year of probation, during which there must be no symptoms, no positive and at least six negative Wassermann tests (ice-box); and, at the end of the year, negative physical and neurologic examination, negative *x*-ray of the cardiovascular stripe, and negative examination of the spinal fluid. Moore is of the opinion that continuous treatment without periods of intermission insures in greatest degree against the possibility of relapses, and especially infection of the central nervous system. For this reason mercury is started before the course of arsphenamin injections is finished and continued to the first injection of the succeeding series of injections. Moore believes that if this plan of treatment could be applied to every case of primary and secondary syphilis, the incidence of asymptomatic neurosyphilis, and in all probability that of clinical neurosyphilis, might be reduced to an absolute minimum. Judging from his data the present level of 20 to 25 per cent. of clinical neurosyphilis might be reduced to 5 per cent. or less. The economic saving to the state, to mention only one of the advantages of this reduction, would be enormous.

Ormsby,[24] employs the following method: In the early stage, before generalization has occurred, three injections of arsphenamin are given with an interval of one day between the injections. The average dose is 0.4 gm., but in some instances 0.5 or 0.6 gm. is given if the patient is large and vigorous. In patients not previously treated the first dose is never more than 0.2 gm. Following this, one month's treatment with mercury, either by injection or inunction, is employed. Six weeks from the last arsphenamin injection, three more are given. In well-developed cases not previously treated, the same procedure is employed, except that after the second series of arsphenamin twelve injections of mercuric salicylate are given at weekly intervals, or their equivalent in inunctions over a period of three months, when a third series of arsphenamin is given as before, this being followed by another three months of mercury. In the second year two series of treatments are given in the Wassermann negative cases as a prophylactic measure. In the Wassermann positive cases the procedure is as outlined for the first year.

Stokes[25] begins treatment with three injections of arsphenamin at intervals of three days followed by five more at weekly intervals, followed by two to four more courses of six injections each at weekly intervals with periods of rest so that from 18 to 24 injections are given during the first year along with a total of 300 inunctions in courses of 40 and 80. In the treatment of early syphilis with sulpharsphenamin by intramuscular or epifascial injection (0.2 gm. in each buttock), Stokes and Behn gave three injections at three day intervals, followed by one injection every five days until eight injections had been given. Following the third injection, inunctions of mercury are begun and continued in courses of 80, bridging the sulpharsphenamin intervals. The second, third and fourth sulpharsphenamin courses follow one another at intervals of six weeks.

Gennerich[26] administers arsphenamin by intravenous injection in dose of 0.2 to 0.5 gm. for men and 0.1 to 0.3 gm. for women, every three to four days for the first four doses and then at intervals of five to seven days for an additional four to six doses. Mercury by inunction or an insoluble salt by intramuscular injection is given for six weeks. Gennerich is very much opposed to the administration of neoarsphenamin in primary and secondary

syphilis and administers small doses of arsphenamin. In the treatment of syphilis in the secondary stage treatment is the same followed by five weeks' rest and four to six more injections of arsphenamin; mercury is not given. If the disease is of more than three months duration another course of six injections is given followed still further by a final course accompanied by the administration of mercury.

Finally mention should be made of the observation of Greene[27] who claims that after syphilis is brought under control, arsphenamin should be administered at twenty-eight day intervals on the basis of theoretical considerations indicating that *Sp. pallida* has a life cycle in which it is resistant during a resting stage of encystment and vulnerable every twenty-eight days as it passes into a more active form. Thomson[28] has advocated a somewhat similar plan consisting of the intravenous injection of neoarsphenamin every three weeks continuously until the Wassermann test yields a negative reaction at which time nercury with chalk is given by ingestion for at least a year.

These various quotations from the literature showing the methods employed by syphilologists in different parts of the world on the treatment of acute, early syphilis in the primary and secondary stages will at least indicate how divergent are the methods employed in America and Europe; indeed, every syphilologist appears to have a method more or less his own. They also show a tendency toward thorough treatment and that dependence is seldom placed upon arsphenamin alone or its substitutes. The subject appears almost in a chaotic state, but such is not the case for those possessing a good working knowledge of the pathology and immunity of syphilis and the pharmacology, toxicology and therapeutic applications and limitations of the drugs employed. With such the treatment may be arranged for each case according to the patient's individual condition, the chief demands being intensive and intelligent treatment of each case during these early stages when the most favorable opportunity is offered for the best therapeutic results. Since there are so many methods advocated it would appear almost superfluous to add others, but, as just stated, everyone seems to have their own and so do I, given here for what help they may be to others.

Author's Method for the Treatment of Syphilis in the Chancre or Primary Stage.—If primary syphilis of human beings were as easily cured as primary scrotal syphilis of rabbits this result could be obtained by a single intravenous injection of about 0.9 gm. arsphenamin (1.5 gm. neoarsphenamin) per 145 pounds; or by a total of 1.3 gm. arsphenamin (1.7 gm. neoarsphenamin) divided into 3 daily doses; or by a total of 2.1 gm. arsphenamin (3.2 gm. neoarsphenamin) divided into 6 doses at three day intervals; or by a total of 2.1 gm. arsphenamin (4.2 gm. neoarsphenamin) divided into 6 injections at weekly intervals. But it is evident that this is not the case and no one can state how much more per kilogram of weight is required by human beings for the complete cure of syphilis in the early chancre stage, but it is a safe guess that at least two to three times as much are required.

From the standpoint of the treatment of primary syphilis, it is helpful to divide the cases into those diagnosed and treatment instituted in the first ten days after the appearance of the lesion when the Wassermann test is negative and the lesion autoinoculable and those after this period, when the Wassermann test is apt to be positive and the lesion less likely to be autoinoculable; the only difference, however, is that the latter type may require more thorough treatment than the former although I usually treat both groups alike on the as sumption that a little more treatment than may actually be required for the former will do no harm. My plan of treatment is as follows for adults of both sexes with genital or extragenital chancres and accompanying lesions and symptoms:

1. A physical examination is made, the urine examined, the patient advised regarding the nature of the infection and given the hygienic directions described in Chapter LXIX with special reference to the care of the mouth.

2. The lesion is treated locally as described on page 947.

3. Three daily successive intravenous injections are given of neoarsphenamin in dose of 0.6 gm. or of arsphenamin in dose of 0.3 gm., the latter being of course in alkaline solution (disodium salt) and sometimes administered in a volume of 30 c.c. with a syringe. The injections are given at least two hours after a preceding light meal and constipation is relieved beforehand.

4. These injections are followed by six more of neoarsphenamin in dose of 0.9 gm. or arsphenamin in dose of 0.4 to 0.6 gm. (the latter if well borne) at the rate of two injections per week.

5. I have not employed sulpharsphenamin, but in cases to whom intravenous injections cannot be given, the plan of Stokes and Behn may be followed: three epifascial injections of 0.4 gm. (0.2 gm. in each buttock) at three-day intervals, followed by an injection every five days until eight injections have been given.

6. Immediately after the last dose of neoarsphenamin, arsphenamin or sulpharsphenamin, mercury by daily inunction is started and maintained for six weeks (42 inunctions). The dose is one dram of 50 per cent. mercurial ointment or 85-per cent. calomel ointment applied as described in Chapter LXIII. If for any reason inunctions cannot be given or if it becomes apparent that they are not being applied regularly and faithfully (as is not infrequently the case), intramuscular or epifascial injections of potassium tartrobismuthate in dose of 0.2 gm. in a vegetable oil or 1 to 1½ grains of mercury succinimid or mercury salicylate in oil are given once a week for six weeks; the tartrobismuthate, however, is much less painful and is always preferred especially for sensitive individuals. The urine is examined every two weeks with weekly inspections of the patient for evidences of mercurialism or bismuth siderosis, etc.

7. This is followed by a rest of four weeks with mild specific medication in the form of protiodid (¼ grain three times a day) or 1 grain of mercury with chalk together with 1 grain of Dover's powder three times a day. Intermissions without specific treatment is considered unwise in order to prevent relapses and infection of the central nervous system. A Wassermann test is then conducted, but, regardless of whether the reaction is positive or negative, treatment is continued. A negative reaction, however, gives a more favorable prognosis.

8. Eight more intravenous injections of neoarsphenamin in dose of 0.9 gm. are now given at intervals of five to seven days; or six intravenous injections of 0.3 to 0.4 gm. arsphenamin at weekly intervals or eight epifascial injections of sulpharsphenamin in dose of 0.4 gm. at the same interval.

9. Beginning with the last dose of arsenical the same course of bismuth or mercury (inunctions preferred) described above is repeated followed by a rest of six weeks with mild mercurial medication by ingestion, when a Wassermann test is made. If treatment had begun in the first ten days of the chancre before the Wassermann test yielded a positive reaction and if the two tests called for in this plan have yielded negative reactions, it is permissible to stop the injections, but to examine the spinal fluid and continue with the treatment described in paragraphs 12 and 14. If, however, treatment was started later when the Wassermann reaction was positive, it is well to continue as follows:

10. Six more intravenous injections of neoarsphenamin in dose of 0.6 to 0.9 gm. every seven days; or four intravenous injections of arsphenamin in dose of 0.3 to 0.4 gm. every seven days or six epifascial injections of sulpharsphenamin may be given in dose of 0.4 gm. at the same intervals.

11. Beginning with the last injection of arsenical, mercury is administered again for six weeks by inunction or injection; bismuth is not given at this time to make sure that the patient receives at least one course of mercury.

12. This is followed by a Wassermann reaction on the blood and an examination of the cerebrospinal fluid for total cells, protein, Wassermann and colloidal gold reactions. If positive findings are observed the balance of treatment must take into consideration the early cerebrospinal infection as described in Chapter LXXVI.

13. Up to this point the patient has received either 23 intravenous injections of neoarsphenamin, a total of 11.7 gms. if each dose has been 0.9 gm.; or 19 intravenous injections of arsphenamin, a total of 7.6 gms. if the dose has been 0.4 gm. (as is usual in my practice); or 24 injections of sulpharsphenamin, a total of 9.6 gms. if the dose has been 0.4 gm. each as advised by Stokes and Behn. At the same time either 126 drams of mercury by inunction or 18 epifascial injections of mercury (18 grains) have been given or 12 epifascial injections of bismuth (2.4 gms.) and 6 of mercury (6 grains) in addition to the mercury taken by ingestion.

14. If the blood serum and spinal fluid tests have yielded negative reactions along with the total absence of all clinical manifestations of syphilis, the patient should be kept under observation for at least one year from this time taking either 1 grain of protiodid of mercury or 3 grains of mercury with chalk per day in divided doses for periods of two months followed by one month of rest and a blood Wassermann test at the end; this means therefore eight months of mercury by ingestion with four Wassermann tests during this period.

If, however, the spinal fluid tests yield positive reactions or, if at any time during the year of probation, the blood Wassermann test yields even a weakly positive reaction, it is my custom to give another course of arsenical injections followed by bismuth or mercury as described in paragraphs 8 and 9 or after the plan described in Chapter LXXVI for the treatment of early neurosyphilis.

Author's Method for the Treatment of Syphilis in the Secondary Stage.—The same plan is pursued as described above for the treatment of syphilis in the primary stage except that it is more prolonged and the iodids are included, because of the wider dissemination of the spirochetes through the body and their longer residence on the tissues with the production of tissue changes. For these reasons the possibility of early neurosyphilis with spinal fluid changes must not be overlooked and it is especially necessary to keep these in mind in any plan or method for the treatment of syphilis in the secondary stage. No case is dismissed without at least one spinal puncture toward the end of a treatment unless this is absolutely refused by the patient; to do otherwise may be a serious error.

1. Treatment is given in succession as described in paragraphs 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 for the treatment of primary syphilis. It is continued with mercury as described in paragraph 11 except that potassium iodid is given in addition by ingestion over the period of six weeks in dose of at least 30 grains per day for women and 45 for men in divided doses as described in Chapter LXV; if not well tolerated, smaller doses are given.

2. This is followed by examinations of the blood and spinal fluid as described in paragraph 12. If all tests yield negative results, one may continue as described in paragraph 14, but my usual practice is to treat as follows during this year of observation:

3. Two months of mercury and potassium iodid by mouth followed at once by four weekly injections of neoarsphenamin in dose of 0.9 gm., or arsphena-

min in dose of 0.4 gm. This is followed by one month of iodid by mouth and mercury by inunction or four weekly injections of potassium tartrobismuthate in dose of 0.2 gm. each or four weekly injections of mercury succinimid or salicylate in dose of 1 grain each.

4. This is followed by two months of rest without specific medication when a Wassermann blood test is made.

5. The course described in paragraph 3 is now repeated even though this last blood reaction is negative.

6. Two months of rest are now given followed by a blood Wassermann test and a second (final) examination of the cerebrospinal fluid. If the latter shows an increase of cells, protein and positive Wassermann and colloidal gold changes, treatment is modified as described in Chapter LXXVI for early neurosyphilis. No case is over discharged without examination of the spinal fluid unless this is absolutely refused by the patient.

Standardization of Specific Treatment of Early Syphilis.—The methods just given are applicable in my experience for the specific treatment of the majority of cases of early syphilis of both sexes infected genitally and extragenitally. They are, however, intensive and may be objected to on the basis of being unnecessarily thorough. I can only state that it is my conviction that early syphilis requires some such thorough treatment if complete and lasting serological as well as clinical cure is to be obtained. It is freely admitted that much less treatment usually suffices for dissipating the lesions and restoring the patient to a state when he or she feel and appear perfectly well, but Wassermann tests conducted by a *sensitive* method may yield positive reactions again within a year or two after cessation of treatment and, in my opinion, this regrettable finding is an index of continued infection and an indication for the resumption of treatment. I would wish to emphasize with all the force at my command that a truly positive Wassermann reaction under the circumstances indicates infection and that the test should be conducted with a method as sensitive as possible with specificity to insure sufficient treatment. The methods of treatment given above are based upon the demands of my new quantitative complement fixation method; less, much less, treatment may result in dissipating the infection to such a degree that less sensitive methods will yield negative reactions, but they are apt to be falsely negative and misleading because insufficient for detecting slight evidences of residual spirochetic infection.

In the usual and average case of early syphilis we can truly treat the disease and largely ignore the patient, because most infections occur in young and otherwise healthy individuals; this is in sharp contrast with the treatment of chronic syphilis when just the reverse usually pertains. But not all cases can be treated alike. Some are intolerant of arsphenamin and its substitutes, requiring smaller doses and longer intervals than usual or indeed, the entire abandonment of arsenical therapy. In others tuberculosis, cardiovascular disease, chronic nephritis, infections of the liver and gall-tracts, etc., may introduce complicating factors demanding a careful choice of medicaments and methods of administration to avoid treating syphilis to the detriment of the patient. It is these exceptions that render difficult and unwise any attempt toward formulating fixed or standard methods of treatment of early syphilis but the problem is infinitely less complicated than attempts of this sort in the treatment of chronic syphilis. The treatment of these exceptional and difficult cases of early syphilis is, however, too important a subject to be briefly dismissed and the subject is discussed with more detail in Chapter LXXVIII.

Minimum of Treatment for Early Syphilis.—It is ordinarily so easy to dissipate the early lesions of syphilis like the chancre, the skin and mucous membrane and associated lesions of the secondary stage that great care must be exercised against concluding that the disappearance of these means that a complete and radical cure of the disease has been accomplished. If in addition the Wassermann tests are conducted by a method lacking in sufficient sensitiveness the danger of under treatment is greatly intensified. Less, much less, treatment than advised in the foregoing sections will cause the disappearance of the lesions and yield negative Wassermann reactions when the tests are conducted according to the original method and especially if plain alcoholic extracts of syphilitic liver or other tissue are employed as antigens. It is far better not to use the Wassermann test at all, unless a sensitive method is employed, because the results are almost sure to be misleading in the way of giving a false sense of security. *Even when the blood Wassermann tests with a sensitive method yield a series of negative reactions, we should advise at least one examination of the spinal fluid for total cells, protein, complement fixation and colloidal gold reactions before dismissing the case as cured in order to avoid the regrettable error of stopping treatment in the presence of residual infection of the central nervous system.* Such experience syphilologists as Fordyce, Rosen, Moore, Keidel, Stokes, Gennerich, etc., have laid particular emphasis upon the thorough treatment of early syphilis is the best means for preventing neurosyphilis. Gennerich[29] has even advised combined intravenous and intraspinal treatment in secondary syphilis; Picard[30] and others have drawn particular attention to the danger of insufficient treatment in relation to infection of the central nervous syphilis and the necessity for intensive specific medication, not with pills and powders, but with our best spirocheticides. In Germany and Austria some syphilologists are even employing malarial inoculations in secondary syphilis for the removal of syphilitic infection of the central nervous system.

Doubtless some cases of early syphilis respond more promptly than others; so many factors influence the disease, as virulence of the infection, hereditary disposition to neural infection, occupational and other injuries favoring localization of the spirochetes, etc., that no one program of treatment can be applied to all cases but it would appear advisable for every physician treating early syphilis to insist upon a certain minimum amount of treatment regardless of how quickly clinical and serological evidences of cure are obtained. For my own part, I believe that the treatment outlined in paragraphs 1 to 12 under the method of treatment for primary syphilis, constitutes the minimum for cases of primary and secondary syphilis with positive complement fixation reactions. I realize that this amount of treatment may be more than required for some cases and especially primary cases in the first ten days with negative Wassermann reactions, but I prefer to possibly overtreat some cases to undertreating a single one if this regrettable error is at all avoidable. Objection may be raised on the matter of expense but few physicians will permit this to interfere with their advice and services. There should not be a fixed scale of prices but the charge arranged according to the financial status of the patient to make possible the prolonged and thorough treatment required. The outrageously high fees demanded some years ago for a "shot" of arsphenamin sometimes making it impossible for the victim to afford a second or third, have no place in the present day treatment of the disease when not one or two, but twelve or more injections, are required as a minimum.

Criteria of Cure of Early Syphilis.—Finally the most important question of all is to decide when treatment may cease; I say *treatment* because I believe *observation* should continue much longer. We should never fail to explain the disease to the patient and the utter impossibility of our being able to state in definite and absolutely safe terms that a radical cure has been accomplished in the sense of complete eradication of every syphilitic spirochete from the body. The patient should know this and if any symptoms or lesions develop in the future not otherwise to be accounted for, he should acquaint his physician with the fact of having contracted syphilis. There are, however, different ways of discussing the subject with the patient: one is the gloomy, pessimistic way tending to create those regrettable incurable "syphilitic scars of the spirit," and it should never be employed. Another is the careless, off-hand, cock-sure way of stating that a cure has been accomplished as certain as death and taxes; it is apt to render some persons careless of their future welfare and it is very frequent indeed, to see individuals with advanced chronic lesions of syphilis who neglected seeking advice for long periods of time and who are dumb founded when informed of the nature of their complaints, because of having been previously assured by their physician of complete cure in some such dogmatic manner.

I believe available evidence indicates that syphilis adequately treated in the primary and secondary stages is frequently cured in the complete and radical meaning of the term and not merely "whitewashed" over; but it will require another ten to twenty years before the results of present day methods can be evaluated in final terms. But I believe our modern methods are at least superior to the older methods of treatment; cures were apparently accomplished by treatment with mercury alone but not nearly as frequently as Ricord, Fournier, Hutchinson and other experts long since gone to their reward for good work well done believed, when modern methods of diagnosis are applied to individuals treated according to their methods and especially examinations of the cerebrospinal fluid and central nervous system.

This subject, however, is discussed at more length in Chapter LXXIX; here we are concerned only with what may be called the criteria of cure after the treatment of acute early syphilis. Only an opinion as follows can be expressed subject to future modification:

1. At least one year of treatment with arsphenamin or its substitutes with mercury or bismuth; at least six years of treatment with mercury and iodids if these alone are employed.

2. The total disappearance of all clinical evidences of syphilis as determine by a thorough physical examination including an examination of the central nervous system.

3. At least one year and preferably two years of observation following the cessation of specific treatment or with occasional short courses of treatment during which four or more blood Wassermann tests with a *sensitive* method have yielded consecutively negative reactions.

4. At least one examination of the spinal fluid during this probationery period in which the pressure is not increased, the total cells not more than 10 per c. mm., the protein tests negative, the Wassermann tests negative with large amounts of fluid and the colloidal gold test negative.

CHAPTER LXXIII

SPECIFIC TREATMENT OF LATENT, WASSERMANN-FAST AND CHRONIC ASYMPTOMATIC SYPHILIS

The most peculiar and least understood of all phases of syphilis are the periods of remission or latency. In cases of untreated syphilis a period of latency follows the secondary stage of one to ten years or longer, usually two to five years, during which the patient may feel and appear normal and healthy; this is called the *early latent period*. In cases of insufficiently treated early syphilis, this latent period is likely to be of longer duration and give a false sense of security to a large proportion of syphilitics. Even after the close of this period when tertiary lesions have developed, periods of remission or latency may occur in the tertiary stage in which lesions subside and the disease is quiescent; these are designated as *late latent periods*. The purpose of this chapter is to discuss specific therapy in cases of early and late latency, as it concerns a very large proportion of syphilitics and offers peculiar and difficult therapeutic problems.

Nature of Latency in Syphilis in Relation to Specific Therapy.—I have already discussed the general nature of latency in Chapter XXXVII; what little we know of the mechanism indicates that the parasites are thrown into a state of reduced activity either by immunological processes, by changes in the life cycle of the organisms, or by a combination of the two. Available evidence indicates that an immunological mechanism is chiefly concerned which is peculiar in that it is largely due to resistance offered by the cells in direct contact with the spirochetes rather than to antibodies in the blood. This cellular resistance is not in the nature of phagocytosis; indeed, there is very little evidence to indicate that phagocytosis plays any important part in the immunity of syphilis. Rather the cells develop some kind of intracellular

change or resistance analogous to the intracellular changes occurring in anaphylaxis. These changes appear to occur only in the tissues directly infected by *Sp. pallida,* rather than in distant organs like the bone marrow, so well known to be an active producer of antibodies in most of the bacterial infections.

Clinical versus Pathological and Serological Latency.—Are these immunological changes curative in the sense of destroying spirochetes? Very probably large numbers of the organisms are actually destroyed, but I believe that complete radical cures are of rare occurrence. It cannot be denied, however, that many syphilitics and especially those in latency following six months or more of treatment in the early stages, live to a ripe old age in fairly good health. This is especially true of syphilitic women who have borne children and is more likely to occur among the colored of both sexes than among the whites. Even in the skin and mucous membranes where the curative activity of these immunological processes is most marked, as shown by the spontaneous healing of the chancre and secondaries, complete eradication of spirochetes may not occur as shown by the occurrence of recurring chancres (chancre redux) in the scars of former chancres and the development of condylomata and even recurrent acute secondaries in about 20 per cent. of untreated cases of early syphilis. It may be that the recurring acute skin lesions are due to periods of spirochetemia, but condylomata and chancre redux are almost certainly due to the renewed activities of spirochetes persisting in the tissues from the time of their initial lodgement.

But aside from these evidences of continued spirochetic activity, there may be no other clinical manifestations during the early latent period of syphilis. The patient may and usually does feel a sense of well being which leads not a few into a false sense of security with neglect of further observation and treatment. But are the spirochetes escaping destruction truly latent? Unquestionably their rate of multiplication and virulence are held in check during this period, but the survivors wage unceasing combat with the immunological forces of the tissues and, in the majority of cases of untreated or insufficiently treated syphilis, slowly but surely make progress during periods in which the equilibrium between infection and resistance is unbalanced in favor of infection, and are especially likely ultimately to produce lesions in the cardiovascular and central nervous systems. But during the first two to ten or twenty years, the lesions may be so small or so situated that symptoms and signs of disease are not apparent, although the incidence or percentage of detection of these depends upon the thoroughness of examination and the skill of the physician. But nevertheless the lesions may be present and this constitutes the great difference between what may be called "clinical latency" and "pathological latency." The former is frequent because of fortuitous circumstances preventing the detection of lesions which may be of microscopic size; the latter is much less frequent in that the spirochetes, while held in check, are not in complete check or latency but slowly and surely making progress as shown ultimately by the production of the multitude of lesions embracing the tertiary stage of syphilis.

Furthermore during these periods of clinical latency the Wassermann reaction may be positive and, indeed, constitute the only sign of persistent syphilitic infection. In the presence of apparent good health, and especially over a period of years, the perfectly natural tendency is to regard positive reactions as due to errors in technic or some cause other than the only true one—syphilis. This is one of the most serious mistakes being made to-day by both physicians and the laity. I do not know of a single reason for the occurrence of technically correct and truly positive Wassermann reactions

under such conditions except syphilis, when the matter of frambesia, and, possibly, leprosy, can be excluded. I have, however, already discussed this subject at length in Chapter XXXIX, but after many years of the closest study of the complement-fixation test in relation to syphilis, I wish to warn with all the strength at my command, against the custom of ignoring positive reactions in cases of clinically *concealed* syphilis. I freely admit that these reactions may be sometimes due to errors in technic, but the tests should be at least repeated before being ignored. Even weakly positive reactions are not to be ignored and any serologist who doubts the accuracy of weakly positive reactions should abandon his method for a better one. Even under the best of circumstances the most sensitive methods may still err on the side of yielding falsely negative reactions, because the syphilitic lesions are so small that not enough "reagin" is being thrown into the blood to enable detection in the test-tube. There is, therefore, a great difference between "clinical latency" and "serological latency." By means of a reliable complement-fixation test possessing the maximum degree of sensitiveness compatible with practical specificity, we are able to detect evidences of continued or renewed spirochetic activity in a larger, a very much larger, percentage of cases than is possible clinically. In other words, the positive Wassermann reaction by an acceptable method constitutes one of the most sensitive signs of concealed or latent syphilis frequently apparent months and years before lesions have grown to such size or developed in such organs as to produce such signs and symptoms as may produce ill health and lead to their clinical detection. I repeat again and again, that *to ignore this sensitive sign of syphilis is a serious mistake;* it should at least lead to further serological tests and more thorough and exhaustive examinations of the patient.

Interruption of Latency by Trauma, Age and Treatment in Relation to Specific Therapy.—If an indefinite period of clinical latency could always be counted upon in syphilis, the question of treatment would be much less important but there is always the danger of the disease springing into renewed activity. We do not know in exact terms what may be the determining factors, but evidence indicates that anything lowering the vitality or resistance of the host, either at a local point or in general, favors a cessation of latency and renewed spirochetic activity. Tissues or organs the seat of over-work and strain or physical trauma are especially apt to develop active lesions. Furthermore, the wear and tear of life, its activities and age tend to break the equilibrium between syphilitic infection and resistance in favor of the spirochetes. It may be that an individual will reach a ripe age before such occurs, but the break is so likely to occur that syphilis in the latent stages is worthy of therapeutic attack if for no other reason, that to lengthen the period of latency and thereby prevent the development of crippling lesions as long as possible, even though complete and radical cure may not be attainable. This, however, like everything else, should be subject to exceptions and the exercise of common sense. For example, in those who have reached the age of 60 years or thereabouts and who are in good health, it may be a matter of wisdom to leave well enough alone; their organs, and especially the kidneys, liver and skin, may not be able to eliminate drugs sufficiently well and thereby render our therapeutic efforts more dangerous than the disease and therefore of doubtful value. Furthermore, their vital organs may be crippled by other infections and render them less able to combat the toxic or organotropic effects of our spirocheticidal drugs. But most important of all, our antisyphilitic drugs may actually stimulate the spirochetes into such activity that their progress is hastened rather than checked (Herxheimer reaction). But among the younger and especially that big class of both sexes

between 35 and 55 years of age, who contracted syphilis ten or more years previously with or without treatment at the time, the question of judicious specific treatment during clinical latency is a matter of importance and in my opinion, is always advisable as "a stitch in time to save nine." And frequently the very first sign of this latency during which so much may be done for the unfortunate victim in the way of *judicious* advice as to the manner of living and specific therapy, is the much maligned, frequently misunderstood and underrated complement-fixation text by an acceptable method!

Principles of Specific Therapy of Latent Syphilis.—How may the dangers of therapeutic Herxheimer reactions be avoided? Largely by starting treatment with the mercurials, bismuth or intramuscular injections of sulpharsphenamin. But may not these compounds have a similar action to the stimulating effects of intravenous injections of arsphenamin and its substitutes? Yes, they may and especially if administered in large doses by intravenous or intramuscular injection but not nearly as much as intravenous injections of the organic arsenicals. But cannot the same effects be secured by instituting treatment with small (0.05 to 0.1 gm.) doses of arsphenamin or neoarsphenamin? Yes, but less efficiently than with mercury and bismuth largely because of the more rapid elimination of the arsenicals. Mercury is less rapidly converted into inert compounds and less rapidly eliminated; I believe it tends to penetrate chronic lesions and localize in them to a better degree than the organic arsenicals, gradually and finally reaching a degree of spirocheticidal concentration even though the blood in general may at no time contain a spirocheticidal concentration. This, I believe, is the secret of success of mercury and bismuth in the treatment of chronic syphilis either active or in the latent phases. The organic arsenicals also tend gradually to penetrate chronic lesions and especially if the rate of oxidation and elimination are reduced by intramuscular injections; but clinical experience shows that Herxheimer reactions can be prevented in most cases by instituting treatment with small doses of mercury or bismuth and the iodids, or small doses of the organic arsenicals before large doses of any are given. Why this is so cannot be stated in definite terms, but it is my opinion that mercury, bismuth and arsphenamin or its substitutes have a special selective affinity for syphilitic exudates and when given in small doses tend to accumulate in the lesions where they finally reach such a concentration as effectually prevents or controls renewed spirochetic activity and eventually brings about spirochetic destruction.

Clinical experience indicates, therefore, that the treatment of latent syphilis should be begun with mild rather than intensive methods, in order that the advance scouts of a therapeutic attack may be sneaked into the strongholds of syphilitic infection to overcome the spirochetes and hold them in check when the heavy attack is opened up. The iodids are good auxiliary scouts for opening up the gates of the forts for the attacking forces in the way of softening or breaking down the organized exudates of the foci. This is true of the treatment of both early and late latent syphilis but especially of the latter. In early latent syphilis and especially when treatment is re-instituted during the first two years after infection following an earlier course of treatment, as when the Wassermann test becomes positive in the second probationery year after having been previously negative, therapeutic Herxheimer reactions are less likely to develop because it is probable that sufficient arsenic and, particularly, mercury have been retained to restrain sudden renewed activities of the spirochetes. But in late latent syphilis this is not likely and, furthermore, the spirochetes may have had sufficient time to acquire enough fastness or resistance to arsenic to counteract the spirocheti-

cidal activity of arsphenamin and its substitutes even though they may be sufficiently sensitive as to be stimulated by them.

After treatment has been begun in this mild manner, later treatment may be as vigorous as advised for the intensive treatment of early syphilis. This, however, is subject to wide variation according to individual cases. In latent syphilis of the young or middle aged possessing a good pair of kidneys and other vital organs in good shape we may follow the opening attack with fairly active therapeutic measures, but whenever there are reasons for surmising involvement or dysfunction of these, as is frequently the case in the aged, it is better to continue with milder treatment over longer periods of time.

Nature of Wassermann-fast Syphilis in Relation to Specific Therapy.—Before, however, taking up the actual treatment of latent syphilis, it may be well to briefly discuss the subject of Wassermann-fastness in relation to specific therapy and especially since this condition is frequently met with among individuals in late latent syphilis showing no detectable lesions or symptoms of the disease. There is probably no subject more perplexing than the clinical and pathological significance of this condition and especially from the standpoint of specific treatment. Wassermann-fastness refers to individuals who have received thorough courses of specific treatment, who feel well and in good health, who may show no clinical signs or symptoms of syphilis but whose blood Wassermann tests yield persistently positive reactions when conducted by acceptable methods. Are these individuals really syphilitic? Should treatment be instituted or may the positive Wassermann reactions be safely ignored? There is a wide divergence of opinion upon these questions and another ten or twenty years will be required to give the answers according to the final fate of those to whom treatment is given and not given. But what is the evidence available at present, as these questions involve the happiness and lives of a very large number of individuals?

In the first place, when are we justified in regarding a patient as Wassermann-fast? The criteria vary greatly in the practice and opinions of different syphilologists. What one physician may regard as a case of Wassermann-fastness because the reaction is positive after a certain amount of specific treatment—say, twelve injections of arsphenamin along with courses of mercury—may not be so regarded by another. Furthermore, one physician may meet with the condition but rarely and ascribe this to some superior quality of his methods for treating syphilis, whereas, in truth, he is being deluded by Wassermann tests lacking in sensitiveness. Again a physician may believe he is dealing with Wassermann-fastness because the tests are conducted with a single amount of serum, as 0.1 or 0.2 c.c. which do not show a possible quantitative decrease of "reagin" or Wassermann antibody nearly as well as quantitative Wassermann tests employing varying amounts of serum, as in my new quantitative method. It is impossible, therefore, to define what constitutes Wassermann-fastness unless we adopt arbitrary standards and my own criteria are, cases whose blood Wassermann tests by my method yield persistently positive quantitative reactions after prolonged and thorough treatment: in early syphilis as described in the preceding chapter; in early latent syphilis as described in this chapter. It is impossible to express the incidence of Wassermann-fast syphilis, because of these wide variations in treatment and sensitiveness of serological tests, but it is safe to say that the condition is not uncommon and sometimes constitutes one of the most perplexing problems in the management of syphilis.

But this is only so when thorough physical and roentgenological examinations fail to disclose evidences of syphilis. As discussed at greater length

in succeeding chapters, thorough examinations of the cardiovascular, central nervous, gastro-intestinal systems, etc., usually disclose clinical evidences of syphilis and it is safe to state that thorough microscopical examinations of the tissues after death of cases of this kind in whom no clinical evidences of syphilis were detectable during life, will disclose evidences of the disease in one or more organs. In the study made by Stokes and Busman of 458 Wassermann-fast syphilitic patients, there were only 10 patients or about 2 per cent. presenting no other evidence of syphilis than their positive Wassermann reactions. The question is really not one of whether these cases are syphilitic, but rather how should they be managed therapeutically? Indeed, Wassermann-fastness is not only a sign of syphilis but usually a sign of progressive chronic syphilis rather than of truly latent syphilis. Therefore, these cases generally require something in the way of specific treatment and it is my practice to advise prolonged specific medication after the plan described in this chapter; I have not yet encountered a case which has not shown some response, as detected not only clinically but more especially serologically with my quantitative complement-fixation test. I really doubt if any but exceptional cases of syphilis are absolutely Wassermann-fast, although in my experience some cases and, especially cardiovascular cases of acquired syphilis and late congenital infections among adolescents and adults, have required as much as five years of persistent effort gradually to remove this state. But, is it advisable and necessary to give treatment merely to remove Wassermann-fastness? Since I believe that Wassermann-fastness is a sign of syphilitic infection and usually progressive rather than truly latent infection, I believe it is whenever our patient is less than 60 years of age and in good general condition permitting the administration of antisyphilitic drugs over a long period of time without injury to the tissues. In elderly individuals however, I believe it is sometimes sufficient to leave well enough alone while maintaining a policy of watchful waiting.

Methods of Specific Treatment of Latent Syphilis.—While many writers have proposed various plans or methods for the treatment of early syphilis, as stated in the preceeding chapter, the literature contains relatively few contributions to the present subject except for some articles discussing the subject in a broad and general manner with the general consensus of opinion that thorough serological tests of blood and spinal fluid and clinical examinations should be made with the institution of specific medication as insurance against dangerous or incurable conditions in later life. One is impressed, however, with the haziness of opinions and the therapeutic measures to be adopted. It is not to be expected, however, that definite plans can be proposed, except possibly for early latent syphilis when we may still treat the disease rather than the patient in many instances. In late latent syphilis so many complicating factors require consideration that only the general principles and examples may be given as in the treatment of chronic active syphilis. The majority of writers appear to be in favor of mixed treatment with arsphenamin and its substitutes, mercury and the iodids. Corbus, for example, in the treatment of latent cases with positive blood Wassermann reactions and negative spinal fluids, advises 50 grains of potassium iodid daily for four weeks, followed by eight weekly injections of arsphenamin, potassium iodid again for four weeks, eight more weekly injections of arsphenamin and eight weeks of daily inunctions of mercury.

Author's Method of Specific Treatment of Early Latent Syphilis.—From the standpoint of specific therapy, early latent syphilis may be divided into two classes as follows: (1) Cases of *untreated* early syphilis in the period of latency following the primary and secondary stages and (2) cases of *treated*

early syphilis in whom positive Wassermann reactions occur during the two or three years following the chancre.

In the *first group* are those individuals who contracted syphilis without suspecting the disease. The chancre may have been so small that it was regarded as a simple non-syphilitic lesion or it may have been hidden from the view or so situated as on the lip or finger, as failed to excite suspicion of its true character. The secondaries may have been light and fleeting. Women are especially likely to fall into this class; also physicians unsuspecting the true nature of an extragenital infection. These cases are not at all infrequent and are usually discovered more or less accidentally by the Wassermann test or clinically by the history, the presence of venereal warts, sore throat, etc. As a general rule the Wassermann reaction is strongly positive and there are reasons for always suspecting a heavy infection and particularly of the central nervous system, cardiovascular system or other organs, although most searching physical examinations may fail to disclose lesions because these cases occur within a two-year period of the time of infection according to this classification. It is not possible to lay down sharp, definite rules of treatment applicable to all cases, because of variations demanded by individual cases, but thorough treatment is indicated somewhat after the following plan (the treatment of exceptional and difficult cases being considered in Chapter LXXVIII):

1. Careful instruction regarding the infectiousness of any open lesions that may occur and especially in the mouth; also in the case of males, the infectiousness of the semen and the strong possibility and probability of transmission to both woman and child in pregnancy.

2. Instruction in general hygienic care, as described in Chapter LXIX.

3. Examination of the urine and the institution of specific medication.

4. If there are no open lesions it is generally advisable to initiate treatment with daily inunctions of one dram of 50 per cent. mercurial ointment or 85 per cent. calomel ointment along with 20 to 40 grains of potassium iodid daily by ingestion for two weeks; this reduces the chances of producing neural Herxheimer reactions.

5. If open lesions are present, as venereal warts or mucous patches, it is well to start at once with the organic arsenicals beginning with small doses and increasing at five to seven day intervals. It is also permissible to initiate treatment with the organic arsenicals in cases without open lesions, but always with small doses at first to reduce the danger of occurrence of Herxheimer reactions.

6. Neoarsphenamin may be given by intravenous injection, beginning with 0.4 gm. and increasing the dose if all goes well until 0.9 gm. is being administered by the fourth injection; at least twelve injections should be given for the first course. If arsphenamin is administered, at least six injections may be given starting with 0.3 gm. If sulpharsphenamin is given, at least eight epifascial injections of 0.4 gm. each may be given.

7. Immediately after the last injection of arsenical, a compound of mercury or bismuth and the iodids should be given for a period of two months. Daily inunctions of mercurial or calomel ointments are preferred along with the oral administration of potassium iodid. If inunctions cannot be prescribed potassium tartrobismuthate may be given by intramuscular injection every five days in dose of 0.2 gm. each, totalling about twelve injections or 2.4 gm. in the two months. Or mercury succinimid or the salicylate may be given in dose of 1 to 1½ grains once a week by epifascial injection, totalling eight injections for the two months. The urine should be examined every two weeks.

8. A rest of one to two months without specific medication may now follow; if, however, the kidneys and general condition are satisfactory, it is well to continue mercurial treatment during this period in the form of 1 grain of protiodid daily in divided doses. A Wassermann test may be made at the end but regardless of whether the reaction is positive or negative treatment is continued.

9. The series of injections of arsenical is now repeated, the balance of treatment for the one to two years being after the method advised for the treatment of secondary syphilis described on page 957 including blood Wassermann tests, cerebrospinal fluid examinations and the same criteria of cure described on page 960. As a general rule more treatment is required for syphilis in this stage than in the secondary stage, because of the longer duration of infection before the institution of treatment.

Cases of the *second group* may occur when the treatment given in the primary and secondary stages of syphilis has been insufficient. As a general rule, there are no discernible open lesions, indeed nothing to indicate persistent syphilitic infection except positive blood Wassermann reactions following one or more negative reactions. Not infrequently, however, spinal fluid changes are likewise present in the form of a weakly positive Wassermann reaction, a colloidal gold reaction of 0 1 2 2 1 0 0 0 0, 2 2 1 0 0 0 0 0 0 or some modifications of these, as well as a slight increase of cells and protein. Unquestionably treatment should be resumed because these are indications of syphilitic infection, possibly of latent infection, but more probably of mild, progressive infection of the cardiovascular, neural system or other organs by spirochetes escaping destruction during the first six to twelve months of treatment. As a general rule the majority of cases of this group occur in the second or third years after infection following a year of treatment and are detected by the routine Wassermann tests advised during this probationery period. Should the treatment be mild as the administration of mercury and iodids by mouth or more vigorous? In my opinion spirochetic activity of sufficient degree to produce a positive blood Wassermann reaction is deserving of fairly active treatment unless contraindicated by complicating factors in certain individuals. As a general rule, this consists of alternate courses of arsenicals, mercury or bismuth, with the iodids, somewhat as follows:

1. The first course if of mercury by daily inunction for one month or an intramuscular injection of potassium tartrobismuthate in dose of 0.2 gm. every five days for eight injections or an epifascial injection of mercury succinimid or salicylate in dose of 1 to 1½ grains every week for four injections. At the same time potassium iodid is prescribed by ingestion in amount of 20 to 60 grains daily in divided doses. This mild initiating course is especially advisable when more than four months have elapsed since the last previous course in order to reduce the chances of producing Herxheimer reactions.

2. This course may be followed by a series of twelve weekly intravenous injections of neoarsphenamin or six of arsphenamin; or eight epifascial injections of sulpharsphenamin at weekly intervals.

3. Beginning immediately after the last injection, daily inunctions of one dram of mercurial ointment or 85 per cent. calomel ointment are prescribed for a period of two months; potassium iodid is given at the same time in a well-tolerated dose. If for any reason the inunctions cannot be given, I give alternate intramuscular injections of potassium tartrobismuthate in oil in dose of 0.2 gm. and succinimid of mercury in oil in dose of 1 grain, once a week for three months (6 injections of each). If mercury cannot be given, I give twelve doses of the bismuth preparation (a total of 2.4 gm.).

4. This course is followed by one month of rest.

5. Mercury is then given by mouth for three months, usually in the form of ⅓ grain of the protiodid or 1 grain of mercury with chalk three times a day after meals.

6. The patient is instructed to bring urine for examination every two or three weeks throughout which also permits one to examine the mouth, etc., for evidences of mercurialism, iodidism, etc.

7. The Wassermann test is now conducted. If positive, these courses or some slight modification of them are repeated. If negative, another short course of arsenic is given (six weekly injections of neoarsphenamin or four of arsphenamin) followed by three months of mercury and bismuth or bismuth alone, etc., as described above in paragraph 3 of this section. This is followed by one month of rest, three months of mercury by mouth and a Wassermann test.

8. In cases of this kind the prognosis must be guarded and the criteria of cure more rigid than usual. I never sanction marriage until the blood Wassermann tests have been negative consecutively over a period of at least one and preferably two years, during which at least one examination of the cerebrospinal fluid has yielded negative results.

9. After the second negative Wassermann reaction has occurred (I do not like the word "secured" because it gives a false impression that this is the sole aim of treatment which is far from being true), mild treatment is advisable during the following one to two years, somewhat after the plan of Fournier's chronic intermittent treatment, namely, alternate courses of two months of mercury and iodids by mouth followed by two months of rest (page 1050).

Author's Method of Specific Treatment of Late Latent, Chronic Asymptomatic and Wassermann-fast Syphilis.—Late latent syphilis is applied to those periods of *clinical* latency developing two to ten, or more years after infection. The patient may appear and feel well although in the majority of cases a thorough physical and roentgenological study discloses evidences of chronic syphilis in one or more organs. These lesions, however, are apparently quiescent although the serological tests of blood and spinal fluid are likely to yield positive reactions. This constitutes clinical latency, because, pathologically, the disease may not be truly latent but insidiously progressive; neither is it serological latency, if quantitative complement-fixation tests show progressively stronger positive reactions in both blood and spinal fluid. In many cases, probably the majority, the diagnosis is made only by the Wassermann test frequently first applied in a more or less accidental manner in the course of routine examinations for life insurance or the diagnosis of some chronic ailment as vague neuritic pains, disturbances of vision or hearing, chronic nephritis, diabetes, cardiac pain, and a host of other ailments bringing the middle aged to the physician for advice. Women who have borne syphilitic children frequently belong to this group, the diagnosis being first made in the course of Wassermann and clinical surveys of a family when evidences of late congenital syphilis are discovered in one or more children. Congenital syphilis of adolescents and adults are likewise generally included in this group, because, while clinical evidences of syphilis may be found, the lesions are apparently quiescent. It includes, therefore, a very large and very important group of syphilitic individuals including those who may be designated as Wassermann-fast cases.

Should specific treatment be instituted in cases of this kind when the only evidences of syphilis may be a history of doubtful significance or value with positive blood Wassermann reactions? I believe that treatment is indicated in the majority of cases in order to leave nothing undone that may be safely

done to prevent the development of chronic lesions in later years that may attack any organ or part of the body and especially the most vital organs of all, as the central nervous system, cardiovascular system, liver, etc.

The first thing to be done is to repeat the Wassermann tests, examine the spinal fluid in some cases and subject the patient to a rigid physical examination especially of the central nervous and cardiovascular systems. If the serological tests of the blood or spinal fluid or both yield positive reactions, I believe that treatment should be instituted even though the results of clinical examinations are negative or doubtful, if the patient is less than 60 years of age and in such condition to render fairly safe the administration of antiluetic drugs in adequate doses. No one plan of treatment, however, is applicable to all; pathological changes in various organs as nephritis, tuberculosis, etc., may require important modifications as discussed in Chapter LXXVIII. Furthermore, cases of this kind frequently display intolerance of various degrees for the organic arsenicals rendering necessary an arrangement of doses and intervals for each case and not infrequently an entire rearrangement of a therapeutic program.

If in addition there are clinical evidences of chronic syphilis of one or more organs, the indications for specific treatment are just so much stronger. But, as just stated, the method of treatment is subject to many variations, according to individual cases; we cannot treat the disease alone, but rather the patient. For my own part, the treatment is essentially that of chronic syphilis with signs and symptoms of the disease. In other words, I prefer to advise and manage cases of *late clinically latent syphilis* with persistently positive Wassermann reactions in exactly the same manner as cases of chronic syphilis showing evidences of progressive lesions. It is true that some may not require as much treatment as the latter and may give a better prognosis, but the underlying principles and treatment are essentially as described in the succeeding chapter.

The plan of treatment herewith submitted is used primarily for individuals under 60 years of age as a means for gradually eradicating the infection or so reducing it as to practically insure a prolonged period of latency amounting almost to the same thing. For older individuals a similar plan may be employed, but generally modified to render it milder and safer from the standpoint of all effects. This plan is as follows:

1. A careful and complete physical examination is made, including an examination of the urine. As a general rule, however, no weak links are found in this class, but in Wassermann-fast cases it is especially important to determine carefully the condition of the liver and kidneys in view of the possible effects of previous treatment.

2. A careful search is made for focal infections with extirpation or correction of these. The patient is instructed in the care of the mouth and general hygiene; the use of alcohol is forbidden and smoking greatly reduced if necessary. Every effort is made to improve or maintain good general health, as free as possible of sustained physical or mental strain.

3. The first course of specific treatment is usually of mercury by inunction and potassium iodid by ingestion for two months. These are to be preferred to intravenous injections of arsphenamin or its substitutes in order to minimize the risks of producing Herxheimer reactions.

Each application of the mercury is one dram of the official 50-per cent. ointment or 85-per cent. calomel ointment; the iodid is begun in daily dose of 15 grains and gradually raised, if possible, to at least 45 grains per day. If inunctions cannot be given, I administer intramuscularly 0.2 gm. or potassium tartrobismuthate in oil or 1 grain of the salicylate or succinimid of

mercury in oil once a week for the eight weeks. If for any reason the injections cannot be given, mercury may be administered by ingestion in dose of ¼ grain of the protiodid four times a day. The urine is examined routinely at frequent intervals and a careful watch maintained for toxic effects from mercury or bismuth and the iodids.

4. This course is followed immediately by one of arsenic. Neoarsphenamin may be given by intravenous injection once a week for twelve weeks, beginning with 0.45 gm. and gradually increasing until 0.9 gm. is given in the fourth and subsequent injections. Sulpharsphenamin is second choice in dose of 0.4 to 0.6 gm. once a week for ten weeks. If arsphenamin is administered the first dose is 0.2 gm. with gradual increases until 0.4 to 0.6 gm. are being given; the course consists of at least 8 injections. My present plan is to alternate intravenous injections of neoarsphenamin with epifascial injections of sulpharsphenamin, giving 8 injections of each over a period of sixteen weeks. This permits the intramuscular reactions to subside and the results, judged largely by the Wassermann tests, have been very gratifying and encouraging. Conrad and McCann[1] write of excellent results following 3 intravenous injections of arsphenamin at weekly intervals along with 20 intramuscular injections of mercuric chlorid at 2–3 day intervals beginning with 10 minims of a 1-per cent. solution in saline; this dose is increased by 2 minims at each treatment until 2 c.c. is given at one time. Advantages claimed for this method of administering mercury are the more accurate grading of doses and practically painless injections.

5. If the treatment is being well borne, it is continued in the form of two more months of daily inunctions of mercurial or 85-per cent. calomel ointment in amount of one dram, along with potassium iodid by mouth.

Up to this point the treatment was begun mildly to prevent Herxheimer reactions and followed up by rather intensive treatment to overcome or check renewed spirochetic activity. From now on the balance of specific treatment may be of milder degree.

6. A rest of two months without specific medication is given or the patient may receive ½ to 1 grain of protiodid of mercury daily in divided doses along with tonic and general medication if required or indicated. A quantitative Wassermann test is then conducted.

7. From now on I am inclined to administer a mixed or combination type of therapy. For two months potassium iodid is given by mouth with three inunctions of mercurial or calomel ointment per week. Each week neoarsphenamin (0.6 gm.) is injected intavenously or, if the patient permits, alternate intravenous injections of neoarsphenamin and epifascial injections of sulpharsphenamin are given. If sulpharsphenamin is refused, 0.2 gm. of potassium tartrobismuthate is given once a week by intramuscular injection. Of course, the urine is carefully examined every two weeks, but I have rarely found it necessary to alter this plan on account of renal irritation.

8. This completes the first year of treatment. If the clinical condition of the patient is good and the blood Wassermann reactions are negative, an examination of the spinal fluid is made. If the results are negative, the patient is put upon ⅓ grain of protiodid of mercury or 1 grain of mercury with chalk with 1 grain of Dover's powder three times a day for three months. This is followed by two months of rest, three months of mercury, two months of rest, etc., for the next three years, very much after the plan of Fournier's chronic intermittent treatment described on page 1050.

9. A clinical examination and a blood Wassermann test are made after each rest period, the patient, however, reporting at frequent intervals during the periods of treatment to be looked over for signs of mercurialism and for

urine examinations. If the Wassermann reaction has remained positive or becomes positive, more energetic treatment is given, consisting of a repetition of the course described in paragraph 7 followed by two months of mercury by mouth, two months of rest, two more months of injections, etc., finally winding up as described in paragraph 8.

10. In Wassermann-fast cases I sometimes alter the plan given in paragraph 7 by injecting intravenously with a syringe a mixture of 0.6 gm. of neoarsphenamin in 10 c.c. of water plus 10 c.c. of a 2-per cent. solution of flumerin (0.2 gm.) or 10 c.c. of 1: 1000 solution of mercurophen (0.01 gm. or $\frac{1}{6}$th grain) once a week alternatingly with intramuscular injections of 0.2 gm. of potassium tartrobismuthate in oil. At the same time potassium or sodium iodid are given in maximum tolerated doses by ingestion.

CHAPTER LXXIV

PRINCIPLES OF THE TREATMENT OF CHRONIC SYPHILIS

Dissemination of Lesions in Chronic Syphilis in Relation to Treatment. Probably the best known form of chronic syphilis is of the central nervous system by reason of the large amount of attention devoted to this subject within the last ten years and especially from the standpoint of various forms of intraspinal therapy. But there is a growing appreciation of the fact that a large percentage of neurosyphilitics also show chronic syphilitic lesions of the cardiovascular system as well and sometimes of the liver and other organs. It is the possibility and probability that important lesions may be present in several organs of vital importance that requires a consideration of the patient as a whole rather than concentration alone on the organ presenting the most active lesions and symptoms, when the treatment of chronic syphilis is undertaken. Why and how *Sp. pallida* selects certain organs and tissues when present in the blood and lymph and carried equally to all parts of the body, cannot be definitely stated; some believe it is a matter of selective strains of the parasite having an elective affinity for certain organs and tissues, but I have discussed this subject with detail in Chapter XXXVI and expressed the opinion that it was not so much a matter of specific strains but rather one of hereditary or acquired injury or predisposition of certain organs and tissues in the nature of areas of reduced local resistance which constituted the chief factors influencing the localization of *Sp. pallida.* Furthermore, I believe it is a mistake to subscribe to the view that the only time of dissemination of *Sp. pallida* is in the early stage of syphilis and that the ultimate fate of the syphilitic is determined at this time according to where the parasites find lodgement during the spirochetemia occurring between the chancre and the outbreak of the secondaries; doubtless this is an important time, but I believe that temporary periods of spirochetemia may occur in the later stages of the disease as well during which the parasites may find lodgement in the tissues injured by over-work, strain and the wear and tear of life subsequent to initial infection and the primary spirochetemia. It is for this reason that advice on the proper manner of living and working

is of importance to every case of early syphilis, in order to reduce the chances of trauma in a broad sense as much as possible.

One of the most instructive chemical studies on the dissemination of lesions in chronic syphilis, is that of Stokes and Busman,[1] of 458 syphilitic patients who had received from twelve to twenty-nine arsphenamin injections combined with mercurial inunctions and all of whom yielded positive Wassermann reactions. In this survey the authors had the great advantage of cooperation of specialists in the neurologic, eye, nose and throat, roentgenologic, laboratory, and other divisions of the Mayo Clinic and the results serve as an excellent example of the practical value of coöperation in the diagnosis of chronic syphilis; the occurrence of multiple lesions in 114 of these patients was as follows:

Of 15 patients with cardio-vascular syphilis:
20 per cent. also had neurosyphilis.
20 per cent. also had osseous syphilis.
20 per cent. also had cutaneous and mucous membrane syphilis.
6 per cent. also had heredosyphilis.
6 per cent. also had splenic, hepatic or gastric syphilis.

Of 21 patients with neurosyphilis:
50 per cent. also had cardio-vascular syphilis (of 6 specially examined).
18 per cent. also had osseous syphilis.
14 per cent. also had splenic, hepatic or gastric syphilis.
4.6 per cent. also had cutaneous syphilis.

Of 30 patients with osseous syphilis:
43 per cent. also had cardio-vascular syphilis (of 6 specially examined).
17 per cent. also had cutaneous syphilis.
13 per cent. also had neurosyphilis.
10 per cent. also had visceral syphilis.

Of 21 patients with visceral syphilis (splenic, hepatic or gastric):
14 per cent. also had cardio-vascular syphilis (of 7 specially examined).
25 per cent. also had neurosyphilis.
14 per cent. also had osseous syphilis.

Of 17 patients with cutaneous and mucous membrane syphilis:
50 per cent. also had cardio-vascular syphilis (of 6 specially examined).
6 per cent. also had neurosyphilis.
30 per cent. also had osseous syphilis.

Of 10 patients with heredosyphilis:
33 per cent. also had cardio-vascular syphilis (only 3 specially examined).
20 per cent. also had neurosyphilis.
20 per cent. also had osseous syphilis.
40 per cent. also had interstitial keratitis.
30 per cent. also had eighth nerve deafness.

From the standpoint of diagnosis, the practical importance of the subject is obvious; from the standpoint of specific therapy, the subject is of scarcely less importance because the untoward effects of the drugs upon certain organs are to be remembered in connection with an appraisal or estimate of the factors influencing the selection and administration of drugs, tolerance for them, dangers attending their use, especially the possibility of producing Herxheimer reactions and paradoxical results, etc., as well as the special therapeutic measures sometimes indicated for disease of certain organs. The subject of dissemination of lesions and their detection is one of primary importance, therefore, as the first step in outlining the treatment of cases of chronic syphilis and not only specific treatment but general treatment and hygiene as well. For example, to plan a vigorous course of intravenous injections of arsphenamin or one of its substitutes for a case of neurosyphilis while ignoring or overlooking important lesions in the cardio-vascular system may be an error by reason of accidents to the latter; likewise, vigorous arsenical treatment of an osseous lesion when the possibility of dangerous neural Herxheimer reactions is overlooked.

Advisability of Thorough Examinations in the Diagnosis of Chronic Syphilis.—Because of this possibility of disseminated lesions in chronic syphilis it may not be readily possible for any one specialist to properly gauge a patient as a whole; the opthalmologist, for example, is naturally mostly interested in the eye lesions and may entirely overlook lesions in the cardiovascular system, liver and other organs; complete diagnosis may be too much for any one physician and frequently requires the coöperation of several specialists and particularly of the opthalmologist, neurologist, roentgenologist and serologist. The complete diagnosis of chronic syphilis is, therefore, a matter of considerable importance and under ideal conditions should provide for any or all of the following examinations of each patient:

1. A very careful personal, family and social history.
2. Blood Wassermann tests by a reliable method combining in greatest degree the maximum of sensitiveness consistent with specificity.
3. A complete examination of the spinal fluid in some cases and especially those whose history or physical condition is suggestive of chronic syphilis but whole blood Wassermann tests yield negative reactions. These examinations should be for pressure, total cells, protein, Wassermann and colloidal gold reactions. In some cases a provocative Wassermann test may be indicated.
4. A complete examination of the urine and especially for albumin, casts, pus and red blood corpuscles.
5. A neurologic examination.
6. An examination of eye, ear, nose and throat.
7. An examination of the skin, mucous membranes, periosteum and bones.
8. A cardiovascular examination, including the physical findings, blood pressure and in some cases, an electrocardiographic study.
9. An examination of the abdominal viscera and especially of the stomach, intestines, liver and kidneys.
10. A roentgenologic study and especially of the heart and aorta.
11. A therapeutic test in some cases.
12. An examination for foci of infection as necrotic teeth, impacted roots, apical abscesses, enlarged tonsils, infected sinuses, etc. The removal or correction of these is advisable in the way of preparatory treatment to reduce to a minimum the chances of ill effects from the administration of arsphenamin and its substitutes and especially dermatitis and allied reactions.

In succeeding chapters, I will mention the chief pathological changes in chronic syphilis of the important vital organs although the matter of diagnosis is not included in a manual of this kind devoted to the subject of treatment; but in many cases the application of comparatively simple tests and examinations may suffice to show that an organ or system is not involved to the extent of warranting serious consideration from the standpoint of treatment. In other words the well-trained physician may handle many cases without assistance, provided he recognizes the advisability and frequently the necessity for a complete survey of this kind before outlining a plan of treatment.

Limitations of the Therapeutic Test.—The therapeutic test is not now employed as frequently as formerly, but since it is of much more importance in the diagnosis of chronic than of early syphilis, it is well to recall its limitations and even dangers. Stokes[2] has recently summarized this subject as follows: "Therapeutic tests in general have meaning only when the patient presents a definite, and, as far as possible, a visible pathologic lesion, on which quantitative estimates of improvement can be made. Mere gain in weight, disappearance of indefinite pains, malaise or nondescript subjective symptoms are usually meaningless. Iodid therapeutic tests, popular with the departing generation, are untrustworthy. So are arsphenamin therapeutic tests. I have made, and seen made, erroneous diagnoses of gumma of the lymph nodes with partial positive Wassermann tests. I have seen tuberculous keratitis confused with syphilitic keratitis, lupus vulgaris, erythematous lupus, sarcoids, and tuberculids make striking improvement under arsphen-

amin. Mercury is probably more nearly immune from such nonspecific effects than either iodids or arsphenamin, although it is well to recall its action in lichen planus, and in occasional cases of sporotrichosis. Carcinoma of the stomach makes false responses to arsphenamin alone and sometimes in combination with mercury. One of the reasons a noted neurologist gave for objecting to the dermatologist as a syphilographer was his ignorance of the false positive therapeutic test for syphilis in multiple sclerosis." Stokes also states that he agrees with Herxheimer and Altman[3] that arsphenamin may produce pseudo-reactions in tuberculous processes analogous to the reactions produced by large doses of non-specific proteins and occasionally create a deceptive effect.

The mere fact that a particular lesion shows some regression under specific treatment does not necessarily mean, therefore, that it is syphilitic. Furthermore, the institution of a therapeutic test by the injection of arsphenamin or one of its substitutes may result in the production of a Herxheimer reaction of the optic or auditory nerves, in the heart, a laryngeal ulcer, etc., the dangers and possibilities of which should be estimated and kept in mind.

Pathology of Chronic Syphilis in Relation to Specific Therapy.—This subject has already been discussed at length in Chapter XXXVIII, but it may be well to recall here that the chronic pathological tissue changes produced by *Sp. pallida* constitute the chief reason why the treatment of chronic syphilis is an almost entirely different problem from the treatment of early syphilis and why individualism in treatment is so much more necessary and important than in the latter. The chronic pathological tissue changes of syphilis may influence the efficacy of treatment, the choice and administration of antisyphilitic drugs, tolerance and untoward toxic effects of the drugs and finally therapeutic expectancy and prognosis.

The chief tissue changes in relation to treatment are those occurring in the blood-vessels consisting of mesarteritis and perivascular infiltrations and fibrosis which may hinder the escape of medicaments from the blood stream and may actually amount to an obliterating endarteritis. Even if these changes are not marked the parasites are apt to be well surrounded with plasma cells, lymphocytes and scar tissue which renders difficult the access of spirocheticides. It is largely for these reasons that the iodids constitute valuable remedies in chronic syphilis by reason of their influence upon such organized and unorganized exudates and for the relief of pain probably by release of pressure upon sensory nerves; also why mercury and possibly bismuth, constitute valuable remedies because the former at least tends to gradually penetrate and accumulate in such lesions until spirocheticidal concentrations are reached; also why small doses of the organic arsenicals frequently repeated are usually better than fewer but larger doses, because a better opportunity is afforded for the penetration of lesions when arsenic is available over relatively long periods of time and, finally, why intramuscular injections of the organic arsenicals are sometimes better than intravenous injections, by reason of slower absorption, slower elimination and consequently more prolonged contact of the spirocheticide with the foci of infection.

Tolerance for drugs and untoward effects following their administration are largely influenced by possible pathological changes due to syphilis and other diseases involving the matter of their metabolism and elimination. The kidneys may be defective, not so much because of syphilis, but by reason of chronic interstitial and parenchymatous changes of other origin; the liver may be defective not only because of syphilitic infection but also by reason of infection of the gall-tracts with streptococci or other organisms. Dysfunction of these organs as well as of the skin, heart, etc., due to chronic syphilis

or other diseases may very materially influence the toxicity or organotropic activity of antisyphilitic drugs or at least, influence their selection and manner of administration in an important manner. Finally, the prolonged administration of the drugs themselves and especially arsphenamin and its substitutes, mercury and bismuth, may result in the production of added pathological tissue changes as discussed in Chapters XLVI, LIII and LV.

The additional tissue changes of chronic syphilis are largely concerned with those produced in the cells of the organ or tissue involved as a result of toxic substances produced by *Sp. pallida* or secondary to the vascular changes and production of inflammatory exudates. These changes are multitudinous and especially in the brain and spinal cord, but it is hardly worth while to mention here the minute changes because they do not primarily influence treatment. They do, however, bear an important relation to therapeutic expectancy and prognosis. For example, in the treatment of tabes dorsalis the knee-jerks and a normal gait may not be restored because antisyphilitic drugs cannot remove scar tissue; likewise sclerosis of the aortic valve and of the coronary arteries may not be removed. What treatment aims to accomplish is to prevent further tissue changes by *Sp. pallida* while hoping for at least some symptomatic improvement. Indeed a new set of symptoms and lesions may make their appearance as a result of healing since the further laying down of fibrous tissue may follow the sterilization of foci; such, for example, may be ascites and other evidences of cirrhosis of the liver following the effectual treatment of syphilitic hepatitis and constituting a therapeutic paradox as pointed out recently by Wile;[4] Stokes states that cicatricial stenosis of the oesphagus and rectum, even of the hour-glass stomach, may occur and he is inclined to believe with Hubert[5] that, so far as the heart is concerned, acute myocardial ischemia, anginal attacks of increased severity, even the development of certain physical signs of aortitis and aneurysm, may be the results of too energetic treatment and too rapid healing.

Principles of the Treatment of Chronic Syphilis.—It is apparent, therefore, from this brief review of the pathology of chronic syphilis in relation to treatment, that many factors may operate against the attainment of successful results. In addition to the pathological tissue changes produced in vital organs by *Sp. pallida*, we may have those so-called physiological changes due to advancing years and the effects of any intercurrent infections to which syphilitics are as much subject as non-syphilitic individuals. We also run the danger of breaking up the immunity equilibrium of latency in our anxiety to cure, without being able to successfully combat an increased activity of aroused spirochetes and resulting in the production of a Herxheimer reaction.

We should, therefore, carefully appraise each case before planning a therapeutic program based upon the age of the patient, an estimate of life expectancy and the influence of handicaps as tuberculosis, chronic nephritis, arterial hypertension, etc.; also an estimate of probable tolerance for antisyphilitic drugs and the probable response to treatment on the part of the most important organs involved.

Our therapeutic program should include a thorough examination to detect the weakest points and most dangerous lesions, with a view to finding all the types of involvement in each case. This may enable us to regulate the life of the patient in such manner as to relieve strain on the weakest points and to conduct treatment in such manner that an early involvement may be checked from becoming later a prominent lesion.

We should use every available means for improving the general condition and to protect against the ill effects of the drugs administered with a correction of those defects likely to produce toxic drug reactions or favor spirochetic

activity. I have in mind such matters as proper attention to the bowels and kidneys, estimating the functional capacity of the latter not only by frequent examinations of the urine, but also by occasional estimations of blood urea and total creatinine; oral hygiene and the extirpation of focal infections; the avoidance of dietary errors, excessive smoking, alcoholism, over-work and worry, sexual excesses, etc. In other words as stated by Stokes, our method should be a general overhauling job rather than a patching job. As he has so well stated, it is well to "protect patients from the small but cumulative insults which too often keep them in a substandard condition under intensive treatment, even though the individual by-effect may not become conspicuous in itself. In late syphilis, in which the margin between treatment requirements and treatment tolerance is often very small, such protective measures may make all the difference between success and failure."

From the standpoint of specific therapy, it is more difficult to adhere to any set or fixed plan of treatment of chronic syphilis than for early syphilis, although it is well and advisable to have a scheme of treatment fixed in mind as a model of routine therapy subject to modification for individual cases, rather than to carry the plan of individualization too far. This is especially true in clinic practice where physicians may be required to manage large numbers of patients in a comparatively brief time; it insures more thorough treatment of these as well as of patients in private practice.

Mercury and the iodids should certainly play a very important part in treatment; likewise bismuth as a substitute for mercury. But the organic arsenicals are likewise of great aid and importance although the intensive methods are required only for the rapid healing of open lesions and the general principle being one of less intensive but more prolonged specific treatment than in the case of early syphilis in which the total dosage of specifics equals and possibly exceeds the amounts given in the latter. Moderation in dosage is imperative and especially in the treatment of chronic cardio-vascular syphilis; treatment should be based largely upon close and frequent observation and examination at intervals for many years and even for the balance of life in order to direct treatment toward the conservation of vital organs essential to life, even though involvement of physiologically unimportant tissues must be overlooked. In other words I thoroughly agree with Stokes who has written that "the essence of the modern treatment of syphilis is system and observation, and in the end those of the modern treatment technics which best perfect the *observational* aspect, will show the lowest ultimate mortality." Even after symptoms and lesions disappear, observation is required for many years and even for the balance of life with as much follow up treatment at least as given to early cases of syphilis, if tolerance permits.

Criteria of Successful Treatment of Chronic Syphilis.—Finally what may be reasonably expected of the modern treatment of chronic syphilis? Of course, our aim is complete cure without producing irreparable or dangerous reactions by the drugs employed. We do not yet know what percentage of cases are being radically cured; probably it is but a small number of the total treated under the best of conditions, but arrest of the disease is apparently attainable in at least 80 to 90 per cent. of cases and symptomatic improvement and life long arrest of progress of the disease may almost amount to the same thing as total extirpation of the infection. Carrying an individual through the fulness of his or her years, with the maximum degree of working capacity and efficiency and the minimum of danger to contacts and society, comes very near to being a successful result and such are obtainable in many cases.

Our patients commonly expect too much. It is not reasonable to expect the removal of the scars or complete arrest in a matter of a few months of an infection that has been progressive for years. It is of little importance that knee-jerks and gait are not restored, that an Argyll-Robertson pupil persists or a murmur of aortic regurgitation is undiminished. It is important, however, that the further loss of function cease, as progressive disturbances of gait or the development of bladder and rectal incontinence, increasing frequency of anginal attacks, increasing size of the liver and attacks of jaundice, etc., depending upon the organ or organs mostly involved. As previously stated, paradoxical effects may be observed in which a new set of signs and symptoms may appear as a result of healing which are readily enough misinterpreted as signs of progressive syphilis, as, for example, the development of ascites in the course of healing of syphilitc hepatitis, optic atrophy as a syphilitic neuroretinitis subsides, etc. As shown in aneurysms, pulsations may cease as mesaortitis and periortitis subside so that structural or anatomical improvement may not follow, at least immediately, upon the disappearance of signs and symptoms, since only time and much of it, can be expected to bring about regressive changes in organs like the cardio-vascular, renal and gastro-intestinal systems which cannot enjoy functional rest for recuperation after infection has been extirpated or controlled. On the other hand the rapid improvement in general nutrition, weight and general health as well as functional improvements and especially of the eye and ear as unorganized exudates are absorbed, sometimes exceeds all expectations and lends great encouragement in general to the treatment of chronic syphilis.

CHAPTER LXXV

SPECIFIC TREATMENT OF VISCERAL SYPHILIS

Having thus reviewed in the preceeding chapter the very important subject of the principles underlying and governing the general and specific treatment of chronic syphilis, the treatment of special types may be now considered. I realize the folly of even attempting to formulate anything approaching fixed or standard methods, but yet, as stated in the preceeding chapter, it is distinctly serviceable to have these in mind, subject to alteration to meet the indications and requirements of individual cases. At least, this insures to a better degree against undertreatment and has greatly aided my own work; I am, therefore, giving in this chapter methods for the treatment of different types of chronic syphilis other than of the central nervous system, which I hope will prove as helpful to others as they have to me.

Specific Treatment of Cardiovascular Syphilis.—Syphilitic infection of the cardiovascular system, and especially of the heart and ascending aorta, is apparently the most common type of chronic visceral syphilis. Indeed, this

is so true that the syphilologist should never neglect to examine or have examined the cardiovascular stripe in all cases of chronic syphilis and the internist should never forget the possible syphilitic basis for many of the chronic diseases of these organs. Owing to the ease and frequency with which invasion and infection of the meninges, brain and cord are detected by examinations of the cerebrospinal fluid, we ordinarily have the impression that infection of these tissues with *Sp. pallida* is the most frequent of visceral involvements; but the incidence of cardiovascular syphilis is higher, both clinically and especially pathologically, as determined by the high percentage of macroscopic and microscopic lesions found after death even among syphilitics presenting no particular clinical evidences of involvement during life. Indeed, it is highly probable that almost all cases of chronic syphilis of many years standing have some infection of the cardiovascular system and especially of the heart muscle and ascending portion of the aorta. This is so because of the inherent or natural tendency and predilection of *Sp. pallida* for localization in the heart muscle, the mesial coat and perivascular lymph spaces of blood-vessels, and particularly of the arteries, and because the heart, aorta and arteries of other functionally active organs like the brain and meninges are so frequently subjected to strain and trauma.

Cardiovascular Lesions of Chronic Syphilis.—A rather large literature has accumulated upon this subject, since Morgagni and other early writers first called attention to the syphilitic nature of aneurysms. Within recent years the studies of Brooks,[1] Howard,[2] Symmers,[3] Warthin,[4] Levison,[5] Babcock,[6] Tyler,[7] Hubert,[8] McKensie,[9] and numerous others have greatly aided in drawing attention to the importance of this subject with improved means for clinical diagnosis during life and detection after death. My pathological classification of these lesions is as follows:

(*a*) Syphilitic pericarditis and epicarditis { Diffuse / Localized (gumma)

(*b*) Syphilitic myocarditis { Parenchymatous / Interstitial / Diffuse (usual)

(*c*) Syphilitic endocarditis—usually of aortic valves with regurgitation

(*d*) Syphilitic sclerosis of coronary arteries

(*e*) Syphilitic aortitis { Without dilatation / With fusiform dilatation / With aneurysm

(*f*) Syphilitic arteritis of peripheral vessels { General arteriosclerosis with or without hypertension. / Local arteriosclerosis. / Aneurysms.

(*g*) Syphilitic phlebitis of peripheral veins { General / Local with thrombosis

In a treatise of this kind detailed descriptions of the gross and pathological tissue changes are not demanded, except insofar as these bear a relation to treatment. While detailed accounts of the histological changes are lengthy and complicated, the subject after all can be reduced to rather simple terms. In other words, the pathological changes produced by *Sp. pallida* in the cardiovascular system are similar in every way to those produced in other organs, namely, (*a*) the production of inflammatory exudates of plasma cells and small lymphocytes, especially around small vessels and lymphatics, except in cases of extreme latency when these may be almost absent; (*b*) the production of albuminous, hyaline, fatty or other degenerations of the parenchymatous cells as a result of spirochete toxins and particularly vascular occlusions, and (*c*) the production of fibrous tissue, as in all chronic inflammations.

As would be expected, that portion of the heart and aorta subject to most strain (the anterior wall of the left ventricle and first portion of the aorta) are

most likely to show involvement. Aortic valvulitis, sclerosis and aneurysms of the ascending aorta are the most frequent vascular lesions; indeed, aneurysms of the aorta and especially of its ascending and arching portions, is so frequently syphilitic that all should be regarded as syphilitic until proven otherwise. While sclerosis of the coronary arteries is of frequent occurrence, yet angina pectoris is only exceptionally of syphilitic origin and heart block is but rarely due to syphilis, although Gaucher[10] and others claim that angina pectoris is frequently of syphilitic origin. However, writers on this subject have not always clearly distinguished between precordial pain due to aortitis and stretching of this vessel and true angina pectoris. Of the peripheral vessels, involvement of the cerebral arteries, and especially of the middle cerebral artery and its branches, is best known because of the frequency of aneurysms, thrombosis and rupture of these vessels with the production of hemiplegia due to the frequency of their involvement and poor support by the cerebrospinal fluid and soft consistency of the brain tissue. Hypertension is so frequently due to chronic cardiovascular syphilis, as shown by Audbry and Nanta[11] and others, that this origin is always worthy of serious consideration and study.

General Treatment of Cardiovascular Syphilis.—This varies greatly according to the requirements of individual cases. But all require warning against sudden or prolonged strain, as in laborious work or strenuous exercise. In many cases, probably in the majority, nothing more is required in the way of general treatment than additional advice against excessive smoking, the excessive use of alcohol and coffee, excessive venereal indulgence and all other forms of high tension activity. The anxiety neurosis so often exhibited by these patients must be combated, as it is sometimes worse in its effects than the infection itself; the patient must be educated to a matter-of-fact attitude and a uniform level of physical and mental strain, with a minimum of periods of sudden exertion, anger, worry, etc. If hypertension exists these and additional measures should be taken to reduce it; as a rule, cases with hypertrophied heart with good compensation do well under treatment and especially small doses of neoarsphenamin by intravenous injection. The key-note is the prevention of sudden or long sustained strain, not only because present lesions may "give away," but also because new areas of infection may be produced or latent foci stimulated into activity.

In severe cases of cardiac decompensation and dilatation, rest in bed with the administration of digitalis, strophanthus, etc., dietary restrictions to prevent increase of weight and to lessen the burden of nitrogenous elimination by the kidneys, dieuretics and other special measures may be required.

Specific Treatment of Cardiovascular Syphilis.—Specific medication is possible and advisable in the great majority of cases. However, as stated by Mock[12] and others, marked prostration, severe and frequent angina and severe decompensation and dilatation are bad risks or positive contra-indications, unless rest in bed combined with judicious general treatment restores the patient to such a state that mild antisyphilitic treatment may be cautiously undertaken.

It is important, however, to institute specific treatment in a mild and progressive manner, rather than administer large doses of arsphenamin or its substitutes by intravenous injection in order to prevent Herxheimer reactions and the untoward effects of the drugs or the excitement of their administration upon blood-pressure and capillaries in general. Most writers are in favor of beginning with mercury and iodids or, at least, depending largely upon prolonged treatment with these, as Dix,[13] Babcock,[14] Etienne,[15] Wile,[16] Groedel and Hubert,[17] Stokes[18] and others. While Vau-

quer, Laubry and Donzelot[19] treat these cases rather energetically with the arsenicals and mercury, the majority of other writers like Mock, Howard[20] Kothny and Müller-Deuham,[21] and Cumston[22] have preferred prolonged treatment with very small doses of arsphenamin and its substitutes, and especially neoarsphenamin, and this appears to be the keynote of success in the specific treatment of these cases, at least, cases far enough advanced to influence the toxic effects of the drugs. Harrison[23] has observed good results in the treatment of myocarditis following deep subcutaneous or intramuscular injections of sulfarsenol (sulpharsphenamin) in dose of 0.3 to 0.48 gm. combined with the administration of mercury and iodid. Herxheimer reactions and cardiac strain from large doses of antiluetic drugs, and especially the arsenicals, may produce an increase of pain, pulmonary edema and anasarca, increased expansile pulsations of aneurysms or rupture of the latter, and such accidents are avoidable by beginning treatment in a mild manner with mercury or very small doses of neoarsphenamin (0.05 to 0.1 gm.) intravenously. Rosin[24] has expressed an opinion in favor of bismuth and, unquestionably, good results are to be obtained with intramuscular injections as a substitute for mercury. The iodids are especially good for the pain of aortitis and coronary sclerosis, but large doses by intravenous injection, as advised by Hoppe-Seyler[25] are unnecessary. Schottmüller[26] has advised weekly intravenous injections of 0.3 to 0.45 gm. of neoarsphenamin until 5 grams have been given, combined with intramuscular injections of calomel or salicylate of mercury in dose of 1 to 1½ grains once or twice a week or intravenous injections of cyarsol or novasurol in separate syringes. Potassium iodid is given for one to two months after each course and two complete courses are given each year for at least three years. In severe cases monthly injections of neoarsphenamin are advised.

With these examples of variation in present methods I may now describe my method for the *specific treatment* of the average case of chronic cardiovascular syphilis under 65 years of age in good general condition, although the urine may show a faint trace of albumin with few hyaline casts:

1. Two months of mercury by inunction every other day in dose of one dram of 50-per cent. mercurial or 85-per cent. calomel ointment with daily doses of potassium iodid by ingestion in amounts of 20 to 45 grains. If inunctions cannot be given, epifascial injections of salicylate or succinimid of mercury in dose of 1 grain or intramuscular injections of potassium tartrobismuthate in dose of 0.1 to 0.2 gm., are given once a week for eight doses.

2. The administration of arsenic is now begun in dose of 0.1 gm. of neoarsphenamin twice a week for three months (24 injections). If well borne, the dose is gradually raised and the whole course generally averages a total of about 5 gm. Arsphenamin is not given because of the greater chances of untoward effects. Sulpharsphenamin may be substituted by epifascial injection giving 0.2 gm. every 5 to 7 days and gradually increasing to 0.4 gm. per dose if well borne so that a total of about 4 gm. are given in the course of twelve weeks. At present I frequently alternate intravenous injections of neoarsphenamin with epifascial injections of sulpharsphenamin. Potassium or sodium iodid is given throughout in well-tolerated doses.

3. The urine is examined routinely at frequent intervals.

4. Immediately following the arsenical course 1 grain of protiodid of mercury a day in divided doses or 1 grain of mercury with chalk combined with 1 grain of Dover's powder, three times a day, are prescribed for a period of two months, the patient reporting at intervals for examination.

5. This is followed by a rest of two months and a quantitative Wassermann reaction. Sometimes in cases of aortitis associated with pain, it is not

advisable to stop specific treatment altogether but to continue with weekly injections of neoarsphenamin in dose of 0.2 to 0.4 gm. or intramuscular injections of potassium tartrobismuthate in dose of 0.2 gm. throughout this period.

6. The course described in paragraph 2 is now repeated, which finishes the first year of treatment.

During this time there has usually occurred great relief from pain, pulsations, etc., along with arrest of the lesions, some regression and especially of early fusiform dilatations of the aorta, and frequently considerable diminution of the degree of complement fixation sometimes amounting to a complete reversal to negative. But specific treatment should not stop; at least one or two courses should be given during the second and third years and in some cases for longer periods, depending upon circumstances, of the following:

7. For two months either (*a*) three inunctions of mercury per week with weekly intravenous injections of neoarsphenamin (0.2 to 0.4 gm.) or weekly epifascial injections of 0.2 gm. sulpharsphenamin or alternate injections of these; or (*b*) alternate weekly intravenous injections of 0.2 to 0.4 gm. neoarsphenamin combined in the same syringe with 10 c.c. of 2-per cent. flumerin (0.2 gm.) or 1:1000 mercurophen (0.01 gm. or $\frac{1}{6}$th grain) with intramuscular injections of potassium tartrobismuthate in dose of 0.2 gm. Potassium iodid is given with either course by ingestion in dose of 40 to 60 grains daily if well tolerated.

This is followed by two months of rest and two months of protiodid of mercury or mercury with chalk by mouth. The course requires six months and two may be given the second year and one the third year.

8. But it is doubtful if specific treatment should be stopped entirely after this time, even though Wassermann tests yield negative reactions. It is generally advisable for these patients to report regularly twice a year for examination and to take at least one course of treatment per year of either of the two courses described in paragraph 7 or at least two or three months of daily inunctions of mercurial or calomel ointments with potassium iodid by mouth. If inunctions cannot be given, intramuscular injections of potassium tartrobismuthate in dose of 0.2 gm. or salicylate of mercury in $\frac{1}{2}$ to 1 grain, for eight weekly injections, may be administered. If these are not required, at least three months of mercury by ingestion per year should be advised as a precautionary measure.

Prognosis in Cardiovascular Syphilis.—The prognosis is, of course, subject to great variation depending upon the location of the lesions, their duration and severity before treatment is instituted. In severe cases the duration of life is ordinarily from two to five years. If specific treatment is undertaken early and the patient is willing to follow advice as to the manner of living, the prognosis is ordinarily quite favorable and many, probably the majority, of patients can be carried along for many years and even to the usual span of life. According to Levinson[27] involvements of the aortic valves and coronary arteries are always serious; Keidel and Kemp[28] state that the prognosis in uncomplicated aortitis is ordinarily quite good when well treated, bearing a relation to the amount, regularity and duration of specific medication. Special care must be exercised in treatment when aneurysms are present to guard against the effects of Herxheimer reactions and toxic reactions. The symptoms are generally relieved while the lesion remains stationary for long periods of time even though it may not recede but remain as early fusiform dilatations. All of these results are worth while and may amount to a symptomatic cure even though total extermination of the infection may not be possible and very probably is of only exceptional occurrence.

Specific Treatment of Syphilis of the Liver. *Mechanism of Infection and the Pathology of Hepatic Syphilis in Relation to Specific Therapy.*—Owing to the large size, rich blood supply and functional activity of the liver, it is to be expected that this organ will be frequently infected with *Sp. pallida.* Symmers,[29] for example, found hepatic lesions in 105 of a series of 314 post-mortem examinations of syphilitics and this incidence was based largely upon macroscopic evidences; doubtless histological examinations would have disclosed a higher incidence. But clinically the incidence is not nearly as high, since infection of the liver may be present without the production of signs and symptoms; it is surprising to note how much damage of the liver may be found at necropsies in individuals presenting no particular evidences of hepatic disturbances during life. There is no evidence indicating the existence of any specific hepatotropic strains of the parasites, but doubtless the subject of previous trauma exercises the same favoring or predisposing influence upon the localization of the spirochetes in this organ as is true of the cardiovascular and other organs. Probably the excessive use of alcohol is important in relation to this matter of predisposing tissue injury, but hepatic syphilis has not been especially observed in relation to chronic alcoholism, as have been some non-syphilitic types of hepatic cirrhosis.

Very probably the liver is most frequently invaded and infected during the initial period of spirochetemia of early syphilis, as occurs in the central nervous system, although we do not have the direct evidence of this, as is furnished by spinal fluid examinations; clinically, not more than 1 per cent. of syphilitics show evidences of the infection at this time in the form of jaundice. But in my opinion the liver may be infected at subsequent intervals by way of the vascular or lymphatic systems.

In vascular infections, and these are doubtless the more frequent, the spirochetes are lodged in the walls of the capillaries and in the perivascular spaces. Pathologically we may recognize a vascular type of hepatic syphilis analogous to the vascular types of neurosyphilis, but clinically this is not detectable except in those rare cases of aneurysm of the hepatic artery and thromboses of syphilized veins. How and why the spirochetes in one case invade the parenchyma in a widespread manner producing diffuse hepatitis in some cases and remain localized in others, cannot be stated, just as we are at a loss to explain why parenchymatous syphilis of the brain (paresis) occurs in some and not in all cases of neurosyphilis.

After lodgement in the liver, acute changes may be produced in the liver cells and these in turn involve the bile ducts; or both, and especially the latter, may be involved by the perivascular exudates. Later fibrous tissue is laid down with another train of secondary changes due to atrophic compression of the parenchyma and bile ducts, as well as loss of nutrition by reason of capillary fibrosis. It is no wonder, therefore, that pathologists have published elaborate accounts of the gross and microscopical changes in hepatic syphilis, because there are so many opportunities for variations according to the degree and duration of involvement, just as elaborate classifications of the lesions of neurosyphilis, and especially of the brain, have been evolved by systematic histological studies. But from the clinical standpoint, and especially in relation to the specific therapy of hepatic syphilis, a relatively simple clinico-pathological classification suffices, and that given herewith has been found adequate and useful:

A. Acute syphilitic hepatitis—diffuse
- Mild icterus
- Severe icterus (icterus gravis syphiliticus or icterus syphiliticus præcox)

B. Chronic syphilitic hepatitis
- Diffuse
- Localized
  - Gummas, including perihepatitis
  - Cicatrices ("hepar lobatum")
- Combined diffuse and localized including amyloid infiltrations.

This classification does not include, therefore, vascular hepatic syphilis or syphilis of the biliary ducts or gall-bladder, because the former is not usually clinically recognizable and the latter do not appear to be primary syphilitic involvements, although the bile ducts are practically always and the gall-bladder sometimes, involved in the course of diffuse and localized syphilis of the liver parenchyma.

From the standpoint of specific therapy hepatic syphilis sometimes presents unusual difficulties because of interference with the metabolism and elimination of specific remedies and especially of arsphenamin and its substitutes. However, when we are reasonably sure of the diagnosis of syphilis and the syphilitic origin of a jaundice, bold specific therapy is indicated and yields gratifying therapeutic results. But in not a few instances the jaundice and other symptoms are not primarily due to syphilis but to a superimposed streptococcus, colon bacillus or other type of infection of the gall-bladder and ducts, and such cases do not improve under specific therapy and indeed, sometimes display a marked degree of intolerance for the organic arsenicals and sometimes for mercury as well. The matter of differential diagnosis of jaundice in syphilis is, therefore, one of considerable importance, as it may be due to syphilis or to other infection, to arsphenamin or other arsenical, or to a combination of these, as discussed more at length in Chapter LI, on the subject of arsenical jaundice. The presence of jaundice, a subicteric state or a history of jaundice always demands unusual care in the outlining of treatment for syphilis; each case must be handled individually, and specific treatment initiated and continued with great care to avoid added injury of the liver, if syphilitic hepatitis is the minor change, or to check the syphilitic process, if this infection is the major one. Naturally when a syphilitic patient presents himself with jaundice we believe that it may be due to syphilis; if he develops jaundice during treatment and especially with arsphenamin, we conclude that it is arsenical jaundice. We may be wrong in both instances, since the jaundice may be due to some other type of infection, carcinoma, etc. Therefore hepatic involvements in syphilis are among the most difficult of diagnosis and sometimes difficult of therapeutic management.

Furthermore, as so clearly described by Wile,[30] the cure of syphilitic hepatitis may be followed by ascites and other symptoms due to the contraction of fibrous tissues following the absorption of syphilitic exudates and gummas; in other words, a paradoxical result may be observed in that the eradication of syphilitic infection may be followed by a train of sequelæ worse than the syphilitic hepatitis. Ascites, however, is inevitable and would have followed anyhow in the absence of treatment; but Wile has properly emphasized the possibility of its early development as the result of specific treatment and as one of the peculiar difficulties that may be encountered in the specific treatment of syphilitic hepatitis.

Insofar as the choice of antisyphilitic drugs are concerned, mercury, bismuth and the iodids are probably better borne than the organic arsenicals, and of the latter, neoarsphenamin is to be preferred to arsphenamin if one may draw this conclusion on the basis of comparative histological studies of the effects of the two compounds upon liver cells. Clinical experience also indicates that arsphenamin is more likely to produce hepatitis than neoarsphenamin, but either drug may be employed if proper attention is given to the matter of dosage.

Specific Treatment of the Hepatitis of Early Syphilis.—This refers to the hepatitis occurring in the late primary and secondary stages of early syphilis. Various explanations have been offered to account for the occurrence of the jaundice. In my opinion it may be due to obstruction of the common bile duct as a result of catarrhal duodenitis, which in turn may be due to a syphi-

litic exanthem of the mucosa; or, it may be the result of constriction of bile ducts by the pressure from edema and cellular exudates in the perivascular spaces invaded by *Sp. pallida*, in addition to involvement of the liver cells at the periphery of the lobules. At any rate, it rarely offers any difficulties in treatment and specific medication may be along the lines described in Chapter LXXII for the treatment of early syphilis, except that preference is to be given to neoarsphenamin rather than to arsphenamin; the diet may be especially of carbohydrates, because liver cells full of glycogen probably do not take up the heavy metals in case the organic arsenicals and mercury are administered. If, however, the patient gives a history of jaundice preceding the contraction of syphilis and thereby showing that the hepatic disorder is probably of bacterial or other origin, greater care will be required in the treatment in the way of less intensive specific therapy.

Specific Treatment of Severe Syphilitic Hepatitis (Icterus Gravis Syphiliticus).—This disease also occurs in early syphilis and runs the course of acute yellow atrophy of the liver. It is apparently an extreme degree of hepatitis due to profound and overwhelming infection of the liver with *Sp. pallida*. How and why the disease occurs is unknown and the condition has no analogue in any other organ, that is to say, no other organ of the body is known to be subject to such a similar degree of profound acute degeneration in the early stages of syphilis. There must be a predisposing change or cause; pregnancy has been associated in some cases. Fortunately the disease is rare and most cases have ended fatally. Wile, however, records the recovery of a case under vigorous mercurial and iodid treatment, and these two drugs appear to be the remedies of choice, since the arsenicals are contraindicated on account of the extreme hepatitis, which may interfere with the elimination of the toxic arsenical metabolites. The diet should be principally of carbohydrates.

Treatment of Chronic Syphilitic Hepatitis.—In the treatment of chronic hepatitis it is my custom first to estimate the functional capacity of the organ by the phenoltetrachlorphthalein and bilirubin tests described on page 705. If the former is eliminated normally and the bilirubin content of the blood is within physiological limits, as they may be and usually are in cases of localized gummas of the liver, the case may be treated in much the same manner as described for the treatment of chronic syphilis in general in Chapter LXXIII, except that special emphasis is to be placed upon large doses of the iodids, like 60 to 90 grains per day by ingestion, if sufficiently well tolerated. If however, the functional tests, the changes in the topography of the liver and the degree of jaundice indicate a severer involvement of the parenchyma due to numerous localized gummas or, as is usual, a combination of diffuse and localized hepatitis, it may be advisable and necessary to change this plan of treatment to consist mostly of mercury or bismuth and large doses of the iodids. Not infrequently the first course of mercury or bismuth is sufficient for clearing up the jaundice so that a course of neoarsphenamin may follow as described; but it is well to use small doses at first (about 0.2 gm.) and cautiously increase them if good tolerance is observed. In such cases, however, epifascial injections of sulpharsphenamin may be better, since absorption is slower with probably less demand upon the eliminative functions of the liver. The diet should be principally of carbohydrates during the icteric stages. In my experience these cases do not offer as much difficulty in the way of specific medication as the following group.

Cases of Syphilis Developing Jaundice during Specific Treatment.—These are the most difficult cases of all and especially from the standpoint of diagnosis of the nature of the jaundice. If this is due to syphilis as a result of a

Herxheimer reaction, that is, an increase of biliary obstruction from increased spirochetic activity, the indications are to push treatment with neoarsphenamin or sulpharsphenamin, as advised by Milian, for the purpose of checking and reducing the inflammatory changes produced by *Sp. pallida.* Such is usually the case when jaundice develops within a week or two after the institution of specific treatment, and especially after the first one or two injections of an arsenical compound. If, however, jaundice develops later in treatment it cannot be considered a hepatic Herxheimer reaction but rather one of the following: (*a*) the result of a superimposed bacterial infection producing obstructive jaundice by catarrhal duodenitis; or (*b*) the lighting up of a previously existing infection of the gall-bladder and biliary system; or (*c*) an arsenical hepatitis; or (*d*) obstruction of the biliary ducts by the products of healing after the manner of Wile's "paradoxical" effects, or (*e*) a coexisting cancer of the head of the pancreas involving the bile ducts and liver or some other superimposed and unrelated disease.

In each case it is advisable to stop specific treatment for the time being. In *a* and *b* special therapeutic measures may be necessary and in *b* the biliary drainage method of Lyon[31] is worthy of consideration as a means for diagnosis and treatment. With the subsidence of the jaundice and associated symptoms, specific treatment may be resumed and especially with mercury or bismuth and the iodids, since one is usually and naturally a little afraid of the arsenicals. If all goes well, however, the latter may be gradually administered and preferably in the form of intramuscular injections of sulpharsphenamin followed later by small, ascending intravenous injections of neoarsphenamin. In the treatment of the *d* kind of case, specific treatment should be continued in the form of large doses of the iodids and active mercurialization, while the ascites is relieved from time to time by tapping as required. As stated above, it is also a good plan to adopt a diet principally of carbohydrates.

Specific Treatment of Syphilis of the Pancreas.—Since syphilis of the pancreas is frequently accompanied by jaundice, it may be well to briefly discuss its specific treatment at this time although it consists of the usual treatment for chronic syphilis described in Chapter LXXIII with such modifications as may be demanded by the coexistence of jaundice or glycosuria.

From the clinical standpoint, syphilis of the pancreas is rare; from the pathological standpoint, however, it is relatively common, according to the investigations of Warthin[32] and Warthin and Wilson. In other words, it may be present without discernible signs or symptoms during life in the majority of cases. Diabetes mellitus, however, may be a result of syphilis of the pancreas or possibly, syphilitic involvement of the medulla and region of the fourth ventricle. Wile[33] has recently summarized the clinical aspects of syphilis of the pancreas and Rosenbloom[34] has discussed the subject very thoroughly in relation to diabetes, including a study of 131 cases of his own; in about 6 per cent. of this series the diabetes was regarded as due to syphilis, while in an additional 6 per cent., syphilis and diabetes were regarded as existing as independent conditions. In other words, diabetes is not usually due to syphilis; but when the blood Wassermann reaction is positive, one may conclude that the patient is syphilitic in addition to being diabetic. This is true at least, of my new complement-fixation test, which Steinfield and I[35] found does not yield falsely positive reactions in non-syphilitic diabetics. On the other hand a positive reaction by this technic indicates that the patient is syphilitic and according to the studies of Warthin, as well as of Sallis,[36] it is entirely likely that the pancreas may be involved.

The jaundice so frequently accompanying advanced syphilis of the pancreas may be due to pressure on the common bile duct by a gumma of

the head of the pancreas or to an associated syphilitic hepatitis. In either case specific treatment should be along the lines described above in which large doses of the iodids and active mercurialization are especially indicated. Even though the parenchyma of the liver is not involved to the extent of interfering with the metabolism of the organic arsenicals, yet if the expulsion of bile from the ducts and gall-bladder is interfered with, there may occur a reabsorption of the arsenic with toxic effects. As long as jaundice is present, therefore, preference should be given to mercury or bismuth and the iodids.

According to most reported cases of syphilitic diabetes, specific treatment does not usually improve the diabetes, because of the destruction of the islands of Langerhans; in other words, we may put out the fire but cannot rebuild the house, and Nature does not appear to be a much better builder herself in this instance. On the other hand, Paullin and Bowcock[37] and others, have observed marked improvement in diabetes during the course of, and probably as the result of specific therapy, the subject being more fully discussed on page 1053.

Specific Treatment of Syphilis of the Spleen.—Owing to the vascularity of the spleen, it is entirely likely that it is infected with *Sp. pallida* as frequently as the liver, although, owing to its relative insensibility in adults and the absence of symptoms, even when it is manifestly involved, clinical syphilis of the spleen is relatively rare in the acquired disease; in the new-born and older children, however, clinical syphilis of the spleen is quite common, probably because of its greater functional activity at this time as well as because of extra severe infection.

The pathology of syphilitic splenitis is quite similar to that of syphilitic hepatitis, in that we recognize an early diffuse splenitis and a late localized, diffused or combined splenitis. The treatment of the former is that of early syphilis in general, as described in Chapter LXXII, and of the latter, that of chronic syphilis described in Chapter LXXIII.

Specific Treatment of Syphilis of the Gastro-intestinal Organs.—Syphilis may involve any portion of the alimentary tract from the salivary glands, gums and tongue to the rectum. Chancres and gummas of the gums are sometimes observed and syphilitic glossitis is relatively common. Syphilitic gastritis is being recognized more frequently as a clinical entity and syphilis of the rectum has long been recognized. Syphilis of the small intestine, however, is comparatively rare, the subject having been recently reviewed by Wile.[38]

The specific treatment of early and late syphilis of these organs is usually that of syphilis in general. Brocq[39] and others have mentioned calomel injections as especially efficacious in late syphilis of the tongue, either in the form of diffuse sclerotic or localized glossitis. In ulcerating gummatous syphilis of the esophagus, pylorus and rectum, however, healing under specific medication may result in strictures, very much as described by Wile in the case of healing of syphilitic hepatitis, producing constriction of the blood and bile channels with ascitis and jaundice. In syphilis of the stomach, the liver is likewise most likely involved and these cases are sometimes difficult to manage from the standpoint of specific therapy. Mercury by inunction, large doses of iodids by ingestion and small, frequently repeated doses of neoarsphenamin by intravenous injection are generally indicated. If inunctions cannot be given, intramuscular injections of the salicylate or succinimide of mercury or bismuth may be substituted; if iodids are not well tolerated by ingestion, they may be tried by rectal injection or better still, sodium iodid may be given by intravenous infusion.

Specific Treatment of Syphilis of the Kidneys.—In view of the vascularity of the kidneys and especially of the rich capillary network of the glomeruli, their functional activity and great susceptibility to various tissue injuries, all of which would appear to favor the localization of *Sp. pallida*, it is a matter for wonderment that these organs are not involved more frequently than is indicated by the incidence of clinical detection during life and by macroscopic examinations after death. *Acute syphilitic nephritis* is occasionally recognized, but chronic or late syphilitic nephritis in the form of vascular lesions, diffuse interstitial fibrosis or localized fibrosis (gumma) is distinctly rare, insofar at least as clinical detection is concerned, although it is possible and, indeed, quite probable, that not a few cases of albuminuria ascribed to antisyphilitic medicaments are in reality due to syphilitic lesions of the kidneys. The occurrence of albuminuria and other evidences of renal irritation or inflammation may have the same varied etiology and significance in relation to specific treatment as jaundice in hepatitis; for example, the urinary changes may be due (*a*) to syphilitic infection of the kidneys and especially if the albuminuria is extremely high and occurring in the first two to six months of syphilis without treatment; (*b*) to chronic syphilis of the kidney; (*c*) to antisyphilitic drugs and especially mercury, and (*d*) to nephritis of non-syphilitic origin. Furthermore, insofar as albuminuria itself is concerned, it is not to be overlooked that this may be due to syphilitic cystitis and not to the nephritis at all.

In the *diagnosis* of acute syphilitic nephritis, Fournier[40] stated that there should be (1) proof of a recent syphilitic infection; (2) the appearance of nephritis with syphilis; (3) a lack of other sources for the nephritis, and (4) such marked evidences of nephritis as very high albuminuria, rapid onset and a tendency to early uremia. To these we may now add a positive blood Wassermann reaction and possibly the presence in the urine of Munk's[41] double refractile lipoids, which, according to Stengel and Austin,[42] may have a syphilitic significance. Unfortunately, Wassermann tests with the urine are not especially worth while and an examination of the urine for spirochetes is of limited value, since these may be present as a result of an exanthem of the bladder wall. Excellent clinical descriptions of this type of nephritis have been published by Munk[43] MacDonald,[44] Hoffmann,[45] Audrey[46] Stokes[47] and Cole;[48] insiduous and fairly rapid onset during the first six months after the chancre and usually about the fifth month, rapid loss of weight, anemia, edema, high albuminuria and Munk's lipoids (as detected by the polarizing microscope) are the chief changes.

In the *treatment of* acute syphilitic nephritis the diet should be bland and sufficiently liberal for raising or at least maintaining general nutrition with a restriction of the proteins. Specific medication is indicated and this should be as vigorous as possible under the circumstances, since a high mortality has been recorded. Most physicians have employed mercury by inunction or injection, but both Stokes and Cole have reported the recovery of cases treated with arsphenamin. It appears to me that the latter is the more rational therapy and since arsphenamin is somewhat less renotoxic than neoarsphenamin, it would appear to be the drug of choice, although the difference in this respect is not so great but that neoarsphenamin may be safely employed. Probably epifascial or intramuscular injections of sulpharsphenamin may be still better since absorption is slower with more gradual elimination. Stokes is of the opinion that arsphenamin is no more dangerous than mercury; since the latter is certainly more toxic for the kidney epithelium, I should say that it is distinctly less dangerous in small doses. The effect of

arsphenamin is likewise much more prompt. The iodids are not required. The treatment of this type of nephritis is, therefore, much like that outlined on page 957 for secondary syphilis, modified, however, to meet the condition of the kidneys by reducing the dosage of the arsenicals: arsphenamin 0.1 to 0.2 gm. and increasing to 0.4 gm. at weekly intervals; neoarsphenamin 0.3 to 0.4 gm. and increasing to 0.6 gm.; sulpharsphenamin 0.2 to 0.4 gm. Courses of any of these should be followed by mercury after the disappearance of the albumin and the whole treatment should be sufficiently prolonged to attempt a radical extermination of the disease. It is scarcely necessary to add that the urine should be examined two or three times a week with quantitative albumin determinations; it is also well to estimate kidney function by occasional examinations of the blood for urea and total creatinin as a better means for adopting in time the special treatment demanded by the threatened onset of uremia. The phenolsulphonphthalein functional test may be likewise of service in this connection.

In the treatment of *chronic syphilitic nephritis* I believe that arsphenamin and its substitutes are likewise indicated, although the treatment may be along the general lines advised for chronic syphilis in general with such modifications in dosage and number of injections as may be indicated by individual conditions. Frequent urine examinations for albumin and casts and occasional blood examinations for urea, non-protein nitrogen and total creatinin are especially in order as guides for the kind and degree of specific therapy. Probably preference should be given to sulpharsphenamin by epifascial injection, because of its slower absorption, and to bismuth, because it is less renotoxic than mercury.

The treatment of syphilis complicated by non-syphilitic nephritis is considered on page 1050.

Specific Treatment of Syphilis of the Bladder and Organs of Reproduction.—To the best of my knowledge the specific treatment of early and late syphilis of the bladder and the organs of reproduction of both sexes is exactly as described for the treatment of early and chronic syphilis in general, since involvement of these organs does not raise any particular questions as to choice of drug and manner of administration, as in the case of syphilis of the liver, kidneys, cardiovascular and nervous systems. In gummatous syphilis the iodids are especially indicated and Thompson[49] states that in gumma of the prostate gland he has observed very satisfactory results from intravenous injections of sodium iodid. Local treatment of lesions of these organs is of little or no use.

Specific Treatment of Syphilis of the Bones, Joints and Lymphatic System.—The specific treatment of syphilitic infection of the bones, joints and lymphatic system is that of early and late syphilis in general, since infection of these organs does not involve any particular points of importance. Indeed, syphilis of the bones is regarded as giving a particularly good prognosis, although syphilis of the joints is much more difficult to cure. According to Horwitz,[50] primary syphilis of the joints in acquired infections is rare and is usually an extension from the shafts; Lacapere and Laurent,[51] however, have observed joint involvements in about 10 per cent. of cases of syphilis in the natives of Morocco, and since the circulation of the synovial membranes and the chances of trauma are such as to greatly favor bacterial embolism, it is a wonder that the joints are not more frequently involved than generally observed. Poehlmann[52] states that in acquired syphilis, about 3 to 5 per cent. of cases have joint complications in the late stage, but these figures are probably a little too high; in children especially the disease may be mistaken for tuberculosis and lead to mutilating operations. The Wassermann reac-

tion is of great value in aiding a diagnosis; tests with joint fluid are not positive unless the blood reaction is positive.

Syphilis of the bones, occurring both as a periostitis or osteomyelitis, responds quite promptly although dead bone must be removed, absorbed or discharged before complete healing occurs. Charcot joints are especially refractory and at best one can but hope for a cessation of progress of the synovitis and arthritis. Periosteal swellings usually disappear, but may leave a residual thickening; lymphatic glands likewise subside, although a fibrotic thickening frequently remains for many years after being apparently sterilized of *Sp. pallida*.

As a general rule, the prognosis in periosteal and bone syphilis is very good, but chronic arthritis is far more refractory. In treatment, the organic arsenicals, mercury (especially by inunction) and large doses of the iodids are indicated after the method given in Chapter LXXIII for the treatment of chronic syphilis.

Specific Treatment of Syphilis of the Skin and Mucous Membranes.—As a general rule, early and late syphilitic lesions of the skin and mucous membranes respond rapidly to specific medication; this is especially true of the early lesions constituting the so-called secondary stage of syphilis. The treatment advocated is that described on page 957; since the lesions are infectious and those about the genital organs and in the mouth especially dangerous from this standpoint, the indications are for rapid sterilization by means of the administration of arsphenamin or its substitutes.

Chronic lesions of the skin, and especially of mucous membranes in the mouth and about the genitalia and anus, are frequently quite refractory to specific medication. Mucous patches and condylomata sometimes resist surprisingly large amounts of antiluetic drugs, but in this connection it is to be remembered that condylomata are not always of spirochetic origin and that patches in the mouth may be due to aphthous stomatitis as well as to spirochetic infection. In indolent ulcerative skin lesions, I have sometimes observed that a few intramuscular injections of 5 c.c. of sterile milk or one of the commercial milk preparations, greatly aided the effects of specific drugs. In chronic lesions the iodids are especially useful and the treatment may be that described for chronic syphilis in general. If eczema or other non-syphilitic skin lesions are present, due care must be taken in the administration of arsphenamin and its substitutes to reduce the chances of producing arsenical dermatitis.

Specific Treatment of Syphilis of the Glands of Internal Secretion.—In syphilis of the suprarenal, thyroid and other glands of internal secretion not already considered, there are no special precautions in specific therapy except possibly in the case of involvement of the thyroid gland with symptoms of hyperthyroidism, when the iodids should not be administered at all or but in small and carefully guarded doses to prevent sudden increase in the thyroid secretions. As mentioned in Chapter LVII, unsuspected adenomas and other involvements of this gland have been brought to the surface clinically, as it were, by the signs and symptoms of hyperthyroidism following the administration of the iodids in the general treatment of syphilis. Possibly we do not keep this in mind as much as we should and especially in the treatment of syphilis of women.

Syphilis of the suprarenal glands is not at all uncommon, as shown by the pathological studies of Warthin; as a general rule, the glands are especially heavily infected in congenital syphilis, myriads of spirochetes being found in sections. Some writers have recently stated that the asthenic states of acquired syphilis, and especially during the secondary stage as well as certain

pigmentations of the skin, are due to spirochetic infection of these glands. The specific treatment, however, is that of early or late syphilis in general, although, if arsphenamin or its substitutes are employed, it is well to be on guard for the occurrence of "nitritoid" reactions (Chapter LI) which Milian and others believe may be due to a sudden deficiency of adrenalin in the blood.

Specific Treatment of Syphilis of the Respiratory Organs.—As is well known, syphilis may involve any portion of the respiratory tract from the nose to the pleural surfaces, including the mediastinal glands. Chancres occasionally occur in the nose; I have seen two cases within the last three years, one in a physician. Chancres have been described in the larynx, but these are extremely rare and of course do not occur at all in the lower respiratory tract. Chronic syphilis of the nose and especially of the nasal bones is one of the best known clinical types; chronic syphilis of the larynx with or without ulceration is likewise well known. Syphilis of the lungs, however, is not recognized clinically in anything near like the frequency of its occurrence; doubtless many cases are regarded as early or closed cases of tuberculosis.

The specific treatment of early and late syphilis of the respiratory organs does not offer any special difficulties or problems; in syphilitic laryngitis, however, due care must be exercised in preventing Herxheimer reactions by initiating treatment mildly with mercury or bismuth and the iodids. I have seen several serious reactions follow the intravenous administration of 0.6 gm. doses of arsphenamin at the outset of treatment. The huskiness of chronic syphilitic laryngitis can be improved by specific medication, but in my experience, is seldom entirely corrected, if present for several years; progressive changes can be prevented, but the fibrous thickening or paralysis of the cords generally persists.

I have known of several cases of tuberculous laryngeal ulcers mistaken for syphilis; great care must be exercised against falling into the error of assuming that all such lesions are syphilitic because of positive blood Wassermann reactions. If an ulcer does not show considerable improvement after a course of mercury, iodids and a few injections of arsphenamin or one of its substitutes, it is not likely to be a syphilitic ulcer.

The presence of tuberculosis of the lungs may complicate the treatment of syphilis, but this is a large and important subject considered with more detail on page 1051.

Specific Treatment of Syphilis of the Ear and Auditory Nerves.—As is well known, syphilis may involve any portion of the auditory system and of special interest, from the standpoint of both diagnosis and specific therapy, is involvement of the labyrinth and the eight or auditory nerve. The high incidence of otologic infection in syphilis is not generally appreciated, although the eighth nerve is now known to be involved much more frequently than formerly surmised as a result of the new labyrinth tests applied by Jones, Fischer and others. Indeed, Jones is of the opinion that eighth nerve mystagmus tests afford the earliest clinical evidence of syphilitic infection of the central nervous system and may indicate this involvement as early as the results of spinal fluid examinations and long before there are clinical evidences of involvement of the optic, oculomotor and other cranial nerves, when periodic tests show a mystagmus (after turning) of eighteen seconds (instead of the normal twenty-six seconds) followed later by one of twelve seconds, etc. Furthermore, these tests are believed to possess value as a guide in treatment and prognosis in that they may show either progressive impairment or improvement as the case may be. Owing to the fact that the labyrinthine artery is a direct branch of the basilar and equally susceptible to infection

with *Sp. pallida*, and since the eighth nerve in its wide ramifications is especially subject to involvement in syphilitic basilar meningitis, it is no wonder that deafness and other manifestations of otologic involvement are not uncommon in syphilis.

The specific treatment of syphilis of the external auditory apparatus and tubal stenosis from pharyngeal lesions, present nothing in the way of special difficulties. But when the auditory nerve is involved in basilar meningitis and especially with extensions to the bony foramina, the matter of Herxheimer reactions and so-called neurorecurrences or recidives, as a result of specific medication and especially with arsphenamin and its substitutes, becomes one of considerable importance.

I am quite sure that arsphenamin, neoarsphenamin and sulpharsphenamin have no direct toxic effects upon the normal or non-syphilized auditory nerve; neither have any reports been yet made of a toxic effect upon this nerve by tryparsamid or other pentavalent compounds, although I am prepared for such since recent reports on the use of tryparsamid in the treatment of neurosyphilis have shown objective and subjective impairment of vision in 5 to 10 per cent. of cases receiving six or more intravenous injections of 2 to 3 grams each. Although there are reports of ears with non-syphilitic labyrinthine involvement apparently made worse, and of syphilitic labyrinthine infections suddenly made stone deaf by the administration of arsphenamin and neoarsphenamin, yet I believe that these accidents were due to Herxheimer reactions of the eighth nerve as a result of an antecedent syphilitic involvement of this nerve, clinically undetected in the first group and known to be present in the second. These Herxheimer reactions have been described in Chapter LVIII; very little increase of exudate in the sheath of the nerve in its bony foramina apparently suffices for producing marked functional disturbances.

As recently stated by Babbitt,[53] great care should be exercised in the administration of arsphenamin and its substitutes when labyrinthine tests show involvement of the eighth nerve; but I believe this is demanded because of the dangers of producing Herxheimer reactions and not because the arsenicals produce a direct toxic effect upon the nerve analogous to the direct effects of atoxyl and tryparsamid upon the optic nerves. When nerve changes occur in early syphilis, as in the course of early infections of the meninges in the first six to twelve months of the disease, ordinary specific treatment, as described in Chapter LXXII for early syphilis, is apparently well borne. But when specific treatment is undertaken two or more years after the chancre, it should be begun with mercury or bismuth and the iodids followed by cautious doses of arsphenamin, neoarsphenamin or sulpharsphenamin for the general treatment of chronic syphilis; this greatly reduces the chances of producing exacerbation of the syphilitic infection with an increase of exudation into the sheath of the nerve and consequent functional impairment. Since tryparsamid and other pentavalent arsenicals are certainly more neurotoxic than arsphenamin and neoarsphenamin, they should not be employed in treatment until more information is available regarding their effects upon the auditory nerve, unless the case is one of paresis, taboparesis or other type of grave neurosyphilis demanding tryparsamid therapy even in the presence of possible injury to the optic or auditory nerves. Indeed, the whole subject of the treatment of syphilis of the internal ear is very closely related to that of the treatment of neurosyphilis in general, which is discussed in the following chapter.

Specific Treatment of Syphilis of the Eye and Optic Nerves.—The specific treatment of early and late syphilis of the eye and optic nerves is essentially

similar to that described for the treatment of syphilis in general. While mercury and the iodids were formerly the chief drugs, there is now a growing consensus of opinion that arsphenamin and neoarsphenamin are to be preferred in practically all cases in association with mercury and iodid. While primary syphilis of the eyelids, conjunctival and cornea is rare, secondary and tertiary lesions are quite common and may involve any of the deeper structures, with the exception of the lens, and particularly the iris, cornea and uveal tract. Involvement of the optic nerves is likewise common and especially in the form of primary atrophy associated with tabes dorsalis; indeed, syphilis of the eye and of the optic nerves is one of the most frequent and important of visceral infections, and not infrequently the presence of the disease is first detected or suspected in the course of ophthalmic examinations.

Examinations of the eye and especially of the fundus should be almost a routine measure before the institution of specific therapy in late syphilis and especially if the organic arsenicals are to be administered. With arsphenamin, neoarsphenamin and sulpharsphenamin these examinations are advisable for the purpose of detecting involvement of the optic nerves in order that their administration may be so regulated to prevent Herxheimer reactions; as will be shortly discussed, there are no reasons at all for suspecting that they exert a direct toxic influence upon the nerves. However, when the pentavalent organic arsenicals like tryparsamid are to be administered, there is an important additional reason for a very careful opthalmic examination because these drugs are capable of injuring the nerves.

In other words, when arsphenamin was first introduced by Ehrlich for the treatment of syphilis, it was received by the ophthalmologists with considerable fear and hesitation since the toxic amblyopias of atoxyl, arsacetin and arsenophenylglycin were still fresh in mind. And true to expectations visual disturbances were soon reported, but it was quickly found that the eye changes were different from those produced by atoxyl. The fundi commonly showed inflammatory exudates in the retina and choroid, associated with hyperemia of the vessels, vitreous opacities and sometimes with hemorrhages; in short, the lesions were due to reactivated syphilitic deposits instead of an essentially degenerative process affecting either the ganglion cells of the retina or the fibers of the optic nerve as produced by atoxyl. Furthermore, but one eye is usually involved, whereas both eyes are usually involved in atoxyl amblyopia and above all, the further administration of arsphenamin is found to clear up the lesions in the majority of cases whereas the additional administration of atoxyl intensified its lesions. Furthermore, while atoxyl amblyopia develops early, the Herxheimer and neurorecurrences of arsphenamin usually develop one or two months later because time is required for the laying down of the increased syphilitic exudates responsible for the lesions and disturbances. In short, the usual disturbances produced by arsphenamin and neoarsphenamin are due to an exacerbation of latent syphilitic involvements of the optic nerve; the visual disturbances of atoxyl are sometimes due to the same process plus, in addition, to a degeneration toxic effect upon the nerve fibers. However, this is now an old story, since the differentiation was made so clearly by McAdams[54] and others ten years ago, but I note in some text-books on ophthalmology that atoxyl is still mentioned for the treatment of syphilitic lesions of the eye. This is a serious mistake because the curative effects of atoxyl are so much less than arsphenamin, neoarsphenamin and sulpharsphenamin that it has no place in the modern treatment of syphilis; furthermore, it has the great disadvantage of producing optic degeneration. It is true that Pomaret and others especially interested in developing the pentavalent arsenicals for the treatment

of syphilis, claim that these effects are due to other impurities in atoxyl. I have already discussed this subject in Chapter XLVI, and believe their claim is erroneous in view of recent experiences with tryparsamid in addition to the results of an investigation by Loevenhart and Young,[55] who showed that arsenicals with an amino-group, or substituted group in a para-position to the arsenic, produced lesions of the optic nerves in rabbits, whereas organic arsenicals with the animo-group in the ortho- or meta-position to the arsenic produced no lesions of the optic nerves in these animals. It would appear therefore, that pentavalent compounds in general are more apt to attack the optic nerve than the trivalent arsenicals. Interest in this subject has been aroused again with the past two years by the use of tryparsamid for the treatment of neurosyphilis and while Lillie believes that the visual disturbances ascribed to it are in reality syphilitic lesions, yet Lorenz and this associates, Woods and Moore, and others, are apparently convinced that tryparsamid may injure the optic nerves and that it should not be administered at all, or very cautiously, when visual disturbances are present. I predict, however, for this drug, a useful place in the treatment of paresis, tabes and taboparesis, and ophthalmologists may expect to be frequently called upon for an opinion of the condition of the optic nerves before it is administered; this subject will be, however, discussed at more length in the succeeding chapter.

In the treatment of syphilis of the eye and optic nerves, arsphenamin, neoarsphenamin and sulpharsphenamin are the remedies of choice; atoxyl and tryparsamid should not be used if the optic nerves show involvement. But it may be asked, are not the Herxheimer reactions excited by arsphenamin and its substitutes equally dangerous? Experience has shown that they are not and that they may be cleared away with addititional specific treatment. Furthermore, they are not to be feared at all in early syphilis of the eye, as in chancres of the external parts or the iritis of the secondary stage. But in all cases of more than a year since infection, the possibility of a Herxheimer reaction is to be kept in mind and especially when previous treatment has been insufficient or none at all has been given. Can they be avoided? In the majority of cases this appears possible by initiating treatment with mercury or bismuth and iodids for a month or two before the administration of the arsenicals is begun, which I believe is the correct principle of treatment of practically all cases of late syphilis as described in Chapter LXXIII. But why not use mercury and the iodids alone in the treatment of syphilis of the eye and optic nerves and thereby make sure of avoiding Herxheimer reactions and optic nerve degenerations? In the first place mercury may produce the same reactions as arsphenamin but less frequently. In the second place, the majority of ophthalmologist appear convinced that mercury and iodids alone are insufficient and far inferior to arsphenamin and its substitutes. Therefore, since the latter compounds do not produce toxic amblyopias and are the superior spirocheticides, and since Herxheimer reactions can be avoided in the majority of cases by proper administration, they are the remedies of choice in the treatment of ocular syphilis, not alone, however, but in judicious combination with mercury, bismuth and the iodids. As stated by Young[65] mercury alone frequently fails to either check or cure the ocular lesions of syphilis and that arsphenamin and neoarsphenamin are the remedies of choice. As is usual in the treatment of syphilis in general, the latter drugs are administered by intravenous injection and sulpharsphenamin by intramuscular injection. Lamb[57] has advocated the treatment of syphilitic iritis, iridocyclitis, kerato-iritis and interstitial keratitis by subconjunctival injections of 1 c.c. of Swift-Ellis serum, but I am convinced

that the beneficial effects are simply due to non-specific protein reactions, since the amount of arsphenamin contained in this amount of serum is certainly too small for spirocheticidal effects. Treatment of syphilitic optic neuritis and especially of primary atrophy, is also conducted by Swift-Ellis intraspinal injections, but I shall refer later to this subject in more detail.

With these introductory remarks, I may now briefly consider the specific treatment of some particular syphilitic lesions of the eye, although it is to be carefully borne in mind that the treatment should be for syphilis in general since the eye lesions are never unaccompanied by lesions elsewhere and particularly of the cardiovascular and central nervous systems. Indeed, the ophthalmologist who treats syphilitic lesions of the eye alone to the disregard of the rest of the body is more reprehensible than the physician who treats chronic syphilis of other organs while disregarding the eye. As a matter of fact the specific treatment of primary optic atrophy is principally concerned with the treatment of tabes dorsalis and other types of syphilitic meningitis and not of the eye itself at all; for this reason the subject of specific treatment is fully considered in the following chapter, but I shall also discuss it here in a brief manner because of its particular interest to the ophthalmologist.

In the specific treatment of *acute early syphilis* of the eye, like chancres of the lids, conjunctivæ and cornea as well as the iritis of the secondary stage, exactly the same measures may be taken as described in Chapter LXXII for the treatment of early syphilis in general. The indications are to check the lesions as quickly as possible by intensive medication. To temporize with mercury and the iodids is a mistake unless some contra-indication to the arsenicals is present of which the only one I can think of in this connection is allergic hypersensitiveness to arsenic. There need be no fear of Herxheimer reactions or degeneration of the optic nerve in these early cases if arsphenamin, neoarsphenamin or sulpharsphenamin are employed. Additional measures are of course required; in chancres, for example, cleansing and local treatment are indicated. In acute iritis, hot fomentations or dry heat and leeches may be indicated for the relief of pain and especially the instillation of atropin for mydriasis until all ciliary irritation has subsided and during the period of changes in the refractive power of the eye. These measures, however, should be always under the control of the ophthalmologist.

In *parenchymatous* or *interstitial keratitis* as well as in *keratitis punctata syphilitica*, best results are observed from mixed arsenical, mercurial and iodid therapy. The older forms of treatment with mercury and iodids alone have more frequently failed than succeeded. For the 2 to 10 per cent. of cases due to acquired syphilis, specific medication may be along the lines described for the treatment of chronic syphilis. For the 80 to 90 per cent. of cases due to congenital syphilis, the treatment described in Chapter LXXVII may be employed, which is essentially similar except that the doses and administration are modified to suit children. Subconjunctival injections of mercury have been used, but I am sure that these are beneficial only insofar as they produce congestion and other non-specific reactions similar to injections of salt solution and sodium saccharinate (Fox). My experience with systemic medication has been so satisfactory that I very much doubt the wisdom and practical value of subconjunctival injections; when non-specific protein stimulation has been indicated, intramuscular injections of sterile milk or one of the commercial milk preparations have yielded the desired effects in my experience. Local treatment in the form of instillations of atropin or dionin may be required to maintain mydriasis and allay inflammation and pain, unless a rise of tension appears when mydriatics should be discontinued.

The specific treatment of other chronic syphilitic lesions of the eye may be along the same lines as advised for chronic syphilis in Chapter LXXIII. It is particularly important to start treatment either with mercury or bismuth and the iodids or cautiously with the arsenicals in order to minimize the chances of producing Herxheimer reactions of the optic nerve. This is especially true if ophthalmoscopic examination discloses evidences of optic neuritis which, according to Igersheimer,[58] may be differentiated from choked disc of intracranial pressure by the presence in the former of vitreous opacities, central scotomas and decrease in dark adaptation.

Of special interest is the specific treatment of *primary optic atrophy*, which is so often associated with tabes dorsalis as to be known as *tabetic atrophy*. As stated above and especially shown by Fordyce and Rosen,[59] there is no proof at all that arsphenamin acts adversely upon the optic nerve; on the contrary its administration frequently arrests the progress of this dreadful lesion and Würdemann[60] has had a similar experience. Fordyce[61] has had particularly good results in the treatment of this condition by a combination of intravenous and intraspinal medication according to the Swift-Ellis method, and states that, in 33 cases, 9 of which were simple optic atrophies, 17 tabetic and 7 paretic types, this treatment resulted in the arrest of the disease and improvement in 12 cases (5 for 2 to 5 years) in a series of 17 with incomplete atrophy of both eyes; in 7 cases with complete atrophy of one eye and partially of the second, 2 progressed and 5 were arrested, while in 8 cases with complete atrophy of both eyes before treatment there was, of course, no improvement. In other words, specific medication cannot do the impossible in the way of restoration of completely destroyed nerves, as the laity and not a few of the profession appear to expect; but if the progress of the syphilitic infection is stopped, nerve fibers partially crippled may recover with the removal of spirochetes and absorption of exudates, with consequent improvement in vision or at least a cessation of further impairment. But this subject intimately concerns the specific treatment and prognosis of neurosphilis in general and I shall continue with its discussion in the following chapter.

CHAPTER LXXVI

SPECIFIC TREATMENT OF SYPHILIS OF THE CENTRAL NERVOUS SYSTEM (NEUROSYPHILIS)

Probably the most important type of visceral syphilis is infection of the central nervous system, not only because it may equal in frequency syphilitic infection of the cardiovascular system and other organs, but because of the seriousness of the chronic infections of the meninges, brain, cord and such of the cranial nerves as may be involved in basilar meningitis. Indeed, cardiovascular and neurosyphilis are the two most common and important types of visceral syphilis and the treatment of the latter is sometimes modified to meet the demands of the former, as when preference is given the Swift-Ellis or some other method of intraspinal treatment when neurosyphilis is complicated by such severe myocardial infection as may render dangerous the intravenous injection of large amounts of arsphenamin or neoarsphenamin. Lowenberg[1] states that in 30 to 40 per cent. of cases of neurosyphilis, some type of syphilitic involvement of the aorta will be found and Stokes, Moore and others have expressed similar opinions.

What is Neurosyphilis?—In a strict sense "neurosyphilis" means the infection of any nervous tissue with *Sp. pallida*. As stated in Chapter XLII, however, I believe that a distinction may be made between *invasion* of these tissues with *Sp. pallida* and *infection* of them. In the former, the parasites are brought to the tissues by the blood and lymphatic circulations, but they do not lodge permanently even though their temporary residence may produce slight but temporary spinal fluid changes and constitute what Nast[2] has so aptly designated as "spinal fluid syphilis" when applied to the spinal fluid changes in early syphilis. In late syphilis, however, the spinal fluid may likewise show profound changes without clinical symptoms constituting "asymptomatic neurosyphilis," sometimes what has been called "asymptomatic paresis," and surely indicative of profound infection. But in early syphilis I believe that temporary residence of *Sp. pallida* may be terminated by natural immunological forces, since it is reasonable to surmise that the parasites are brought to these tissues during the spirochetemic stages of syphilis, while marked spinal fluid or clinical evidences of infection are found in not more than 40 to 60 per cent. How and why the others escape are questions that involve the matter of specific tissue strains of *Sp. pallida*, hereditary and acquired reduction of tissue resistance, etc., which have been already discussed in preceeding chapters.

Since syphilitic infection of the peripheral nerves is rather uncommon, the term "neurosyphilis" has become, by reason of common usage, practically confined to infection of the brain, cord, meninges and such of the cranial nerves as may be involved inside of the cranial cavity by these processes and especially in basilar meningitis, or in their bony canals. The term has replaced the older words "metasyphilis" and "parasyphilis" of the brain and cord, since it has been established that the diseases are due to the actual presence of the parasites rather than to various other agencies held responsible prior to the discovery of *Sp. pallida* itself by Schaudiun and especially the presence of the parasites in the brain and cord by Noguchi and Moore. Neurosyphilis, therefore, as commonly applied, refers to infection of the meninges, brain, cord and cranial nerves with *Sp. pallida* in which the evidences are expressed by spinal fluid changes, by signs and symptoms or, most commonly, by a combination of these.

Incidence of Neurosyphilis.—During the past ten years numerous investigators have shown that spinal fluid changes of varying degree occur in as high as 60 per cent. of *untreated* cases of syphilis during the first six to twelve months of the disease; as a result of adequate specific medication during this first year, the incidence is ordinarily reduced to about 25 per cent., this subject having been reviewed in detail in Chapter XLII. Just what proportion of syphilitics treated by the older methods, consisting of the administration of mercury and iodids after the methods of Fournier, Hutchinson and others, show laboratory and clinical evidences of neurosyphilis, cannot be stated, but it is probable that the incidence is in the neighborhood of 40 per cent. under such methods of specific medication. At the present time, about 20 to 40 per cent. of uncured cases of chronic latent syphilis will show spinal fluid abnormalities, the lower figure (20 per cent.) occurring among those known to have had intensive treatment with arsphenamin and mercury during the first year of the disease. Our figures on the incidence of neurosyphilis, based entirely upon clinical signs and symptoms, are much less definite because the detection of these varies so greatly with the knowledge and experience of the physician making the examination. If one were to base an estimate upon the incidence of such well-defined types as tabes, paresis, tabo-paresis, cerebrospinal syphilitic meningitis (diffuse and localized

including the cranial nerve involvements) and such vascular lesions as the thromboses and hemorrhages, the incidence would be probably in the neighborhood of 10 per cent., as recently estimated by Solomon.[3] But when one recollects in this connection the minor signs and symptoms as well as the atypical cases, that may be detected by expert neurological syphilologists, I am inclined to believe that what may be called the *clinical* incidence of neurosyphilis, is in the neighborhood of 10 to 20 per cent. of cases of chronic syphilis and therefore not very much below the incidence of *spinal fluid* syphilis.

Is the Incidence of Neurosyphilis Increasing? *Neural Infection in Relation to Specific Therapy.*—This raises the question whether the incidence of neurosyphilis is increasing. Undoubtedly the *detection* of neurosyphilis during the past ten years has greatly increased owing to advancing knowledge of the clinical manifestations and spinal fluid changes. But is the incidence actually increasing over what it was fifteen years ago and before the introduction of arsphenamin and its substitutes for the treatment of syphilis? Many physicians have stated that this is actually the case and have directed attention to the increasing frequency of paresis or preparetic states in comparatively young men and women within a few years after infection. Others like Roch[4] believe that arsphenamin and its substitutes stimulate latent foci of infection into activity; others believe that rapid destruction of spirochetes in the early stages by the organic arsenicals prevents antibody production or other immunological changes favoring resistance and latency with the result that spirochetes escaping destruction are better able to infect the central nervous system; still others believe that the vascular effects of arsphenamin produce capillary injuries in the brain, cord and meninges favoring the dissemination and lodgement of the spirochetes. Hata[5] states that the incidence has certainly not been decreased by treatment with arsphenamin and Fordyce and Rosen[6] believe that there has not been a true increase during the past ten years, but only an apparent increase due to more systematic investigations and a more thorough knowledge of this special type of syphilis.

I believe that it is highly probable that the incidence of clinical and spinal fluid neurosyphilis has actually increased during the past fifteen years, largely if not entirely as a result of wrong methods for treating both early and late syphilis with arsphenamin and its substitutes. For the first five to ten years after the introduction of arsphenamin, the drug was not usually given in sufficient amounts; it was altogether a too common practice to depend upon one to four injections which usually sufficed for dissipating the manifest lesions and even reversing temporarily insufficiently sensitive complement-fixation reactions from positive to negative. But apparently one result has been that, in not a few cases of early syphilis so treated, the consequent reduction in the number of spirochetes depressed immunological reactions and resistance enabling the surviving parasites to produce more widespread infection including the tissues of the central nervous system. From my histological studies I have seen no evidences of vascular injuries from arsphenamin and neoarsphenamin in the doses ordinarily employed in our intensive methods for the treatment of early syphilis; neither are there any evidences of adverse effects upon such of the cranial nerves so commonly involved in neurosyphilis, as the optic, oculo-motor and auditory nerves. For these reasons I believe that the adequate treatment of early syphilis, by not a few, but a large series of injections of arsphenamin and its substitutes, is the best guarantee against the subsequent development of both spinal fluid and clinical neurosyphilis, as discussed in Chapter LXXII, and maintained

by the majority of syphilologists including Fordyce and Rosen, Swift, Stokes, Schamberg, Sicard, Gennerich, Wechselmann, and others mentioned in preceeding chapters, as well as Harrison,[7] Mott,[8] Riddoch,[9] Scott and Pearson,[10] Christian,[11] Lowrey[12] and numerous other writers in America, England, Germany, France, Italy and other parts of the world. As between Fournier's old chronic, intermittent but thorough and prolonged mercurial medication and present-day haphazard, too brief and inadequate treatment with a few injections of arsphenamin or neoarsphenamin, I believe the former is the better treatment in the final analysis and especially from the standpoint of infection of the central nervous system; but with more intensive and adequate methods for the treatment of early syphilis with arsphenamin and its substitutes, I believe that Fordyce is correct in his belief and statement that the incidence of neurosyphilis has not actually increased.

In chronic syphilis, however, arsphenamin and its substitutes are so much more likely than mercury to stimulate latent foci of infection into activity, that is, produce neural Herxheimer reactions, but there can be no denial of the fact that these compounds have increased the incidence of such neurorecurrences when administered to cases of chronic latent syphilis in large doses by intravenous injection; even latent cases of tabes dorsalis and other infections of the cord and brain may be stimulated into activity by intravenous injections of large doses of arsphenamin. These in turn may conceivably favor the spread of the infection from these foci and especially if the follow-up therapy is inadequate for checking the renewed spirochetic activities. These effects, however, are not peculiar of arsphenamin and neoarsphenamin alone; mercury and other spirocheticides have a similar action when given in large doses. But the fact remains that arsphenamin and its substitutes are most likely to produce neural Herxheimer reactions or neurorecurrences and neurorecidives with the result that their incidence has increased during the past ten years. But these untoward effects are usually preventable by initiating the treatment of chronic syphilis with mercury or bismuth, very small doses of arsphenamin or with intramuscular injections of sulpharsphenamin followed by larger doses. In the treatment of both acute and chronic syphilis, therefore, the manner or method of administering arsphenamin or its substitutes apparently bears a relation to the incidence of neural infections.

Some writers have maintained that the old custom of allowing the secondaries to develop for diagnostic purposes before mercurial treatment was instituted, resulted in fewer neural and cardiovascular infections. This may be actually true since such practice afforded maximum opportunities for the development of immunological defenses, but the incidence of neural and cardiovascular syphilis under this plan was so high that no one should seriously consider a renewal of the practice in preference for our present day methods for the intensive treatment of early syphilis by which there are excellent chances for the complete extirpation of the disease. As stated in Chapter LXXII, I believe this is the sensible plan when the general condition of the patient admits intensive medication, as is true with the great majority of early syphilitic infections. But a few haphazard injections of neoarsphenamin may be actually harmful in the final analysis because they kill off only enough spirochetes to dissipate the external lesions without complete sterilization, with the result that the patient is denied the benefit of maximum immunological defense with the increased danger of wider dissemination of surviving parasites; hence the great responsibility of physicians undertaking the treatment of early syphilis and the necessity for thorough and intensive specific medication.

Time of Occurrence of Neural Infection.—As discussed in Chapter XLII, numerous investigators have shown that spinal fluid changes indicate that the tissues of the central nervous system and especially the meninges, are invaded by *Sp. pallida* in the majority of cases of early syphilis unless the infection is intensively treated during the chancre stage. If the disease is untreated until the secondaries appear, I see no reason for doubting that in practically all cases the spirochetes are brought to these structures by the blood and lymphatic circulations although spinal fluid evidences may not be found in more than 70 per cent. because the invasion in some cases meets with sufficient resistance on the part of the tissues to prevent permanent lodgement or infection. The specific treatment of primary and secondary syphilis apparently results in the cure of many of these early neural infections to the extent that spinal fluid abnormalities are reduced to about 25 per cent. in the first two years of the disease and additional treatment frequently results in the further reduction of this incidence; certainly, as stated by Wiesel[13] and others, cases of precocious neurosyphilis, with the development of clinical signs and symptoms of neurosyphilis and abnormal spinal fluid changes within a few years after the chancre, are the most difficult cases to control and require a most intensive therapy in which it is well to combine intraspinal with intravenous medication, as advised by Gennerich.

Fordyce and Rosen[14] are convinced that, if the spinal fluid shows no abnormalities at the end of this time, the patient can be assured that neurosyphilis will not develop in the future and this greatly aids the mental comfort of many individuals who have prominently in mind the terrors of paresis and tabes dorsalis. Finger and Kyrle[15] and others mentioned in Chapter XLII also state that negative spinal fluid findings at the end of the secondary stage tells the story and that a reversal to positive during subsequent years is of rare occurrence. Indeed, most students of this subject have subscribed to these views and, since the late Dr. Fordyce[16] has had a particularly rich experience and has been able to follow up some cases for at least ten years, his opinion commands the utmost confidence and respect. It is always advisable, therefore, to examine the spinal fluid at the close of the treatment of early syphilis because negative findings are so important that the mental relief and comfort more than compensate for the inconvenience attending the spinal puncture, whereas if positive findings are obtained, it is important to continue specific medication.

But I doubt the wisdom of being too sure about the matter of subsequent neural involvements. If we could be absolutely sure of the complete eradication of all early infections, the matter would be closed of course in a final and definite manner, but such is not the case. Negative spinal fluid examinations are not an absolute criterion of absence of infection of the tissues of the central nervous system, just as the clearing up of abnormal changes is not an absolute criterion of cure of neural infection. Deep parenchymatous infections may not show spinal fluid changes; neither may a few, scattered, light and early superficial vascular and localized meningeal involvements. In other words, it may be possible for small latent foci of residual infection to escape detection; I know positively that two cases in my own practice showed spinal fluid changes two and three and a half years, respectively, after negative findings at the end of the first year of intensive treatment of early syphilis. Furthermore, I believe that periods of spirochetemia may occur during the chronic stages of syphilis, that is, the presence of spirochetes in the blood as indicated by the positive results following the injection of rabbits with the blood of such cases, and I cannot understand why the central nervous system may not become infected at this time, even though these tissues apparently escaped

during the early or initial period of spirochetemia. Unquestionably the experience of Fordyce and his colleagues justifies us in stating to those individuals showing no clinical evidences of spinal fluid abnormalities of neurosyphilis, that in all probability they have escaped this type of infection and assuring them with considerable confidence that they need not fear subsequent infection even though there may be residual infection somewhere in the body, but we must avoid being too dogmatic and sure since it may not be possible to detect small or latent foci in the central nervous system which may spring into activity at a later time as stated by Vincent;[17] neither should we neglect to carefully examine the central nervous system for evidences of such when patients return at intervals for examination. We should not neglect additional spinal fluid examinations when there are the slightest reasons for suspecting neural involvement with negative blood Wassermann reactions, even though the spinal fluid on a former occasion showed no abnormal changes.

Pathology of Neurosyphilis in Relation to Specific Therapy and Prognosis.—Nothing is more essential for a proper understanding of the problems and difficulties of the treatment of neurosyphilis, and for a correct understanding of its possibilities and prognosis, than a good working knowledge of the fundamental pathological changes. Numerous elaborate and valuable histopathological studies have been made with the introduction of many new terms describing the finer points of cellular changes which tend to confuse the subject, but comparatively few of the essential facts concerning the chief tissue changes suffice for the present purposes and the clinico-pathological classification given on page 524 has been found to fulfill practical needs in this subject.

It would appear that *Sp. pallida* may attack any portion of the central nervous system although some portions are infected much more frequently than others. For example, infection of the parenchyma of the cerebrum and overlying meninges is common, usually resulting in a symptom-complex designated as paresis; the nerve cells of the cerebellum, however, are much less frequently involved. In the spinal cord the parasites frequently attack the posterior nerve roots with subsequent ascending degeneration of the posterior columns, producing the symptom-complex known as tabes dorsalis, whereas the motor nerves and anterior horn cells escape, the whole disease being one of the sensory system. Not infrequently the histopathological changes detected after death are much severer than estimated during life, because infection may occur in areas of lesser physiological importance and producing either no signs or symptoms at all or signs which are no detected or classified at present owing to deficiencies in our knowledge of the functions of some portions of the brain. Regarding the essential pathological changes in the meninges, blood-vessels and parenchyma, I can do no better than refer the reader to an excellent recent resume of the subject by Solomon;[18] also brief reviews recently published by Kaliski and Strauss,[19] Redlich,[20] Grinker,[21] Stoll,[22] and others in relation to diagnosis and treatment.

From the standpoint of treatment, the most satisfactory results are observed in the meningeal and meningovascular types of the disease. These include the large number of syphilitics showing spinal fluid changes in early syphilis but without symptoms, who improve or apparently are cured during the course of routine treatment; also the types with symptoms commonly designated as cerebrospinal syphilis. In this category we may also include early cases of tabes dorsalis when the disease is largely in the form of localized meningitis of the posterior roots with various shooting pains in different parts of the body and before degeneration of the ganglia and posterior spinal

columns has occurred. With the subsidence of the meningeal changes under intensive systemic treatment, the irritative symptoms of excrutiating pains, bladder disturbances and various crises, frequently disappear quite promptly, with a return of the spinal fluid to normal. In other words, best results in the treatment of neurosyphilis are to be expected in the meningeal rather than the parenchymatous forms, apparently because the drugs are brought so intimately in contact with the parasites by the rich blood supply of the pia; also in acute rather than chronic meningeal and vascular types, before thickening of the capillaries has taken place. Even mild treatment with mercury and iodids may apparently suffice, although more intensive treatment with bismuth or arsphenamin or its substitutes, mercury and iodids assure a much larger percentage of recoveries. Some cases, however, are more refractory even to intensive intravenous therapy, although some of these respond to a combination of intravenous and intraspinal treatment.

The lesions of parenchymatous neurosyphilis of which paresis is the chief type, are much more refractory to treatment. Why this should be is not thoroughly understood. It is true that the brain is heavily infected as shown by histological and inoculation tests, but with such a powerful spirocheticide as arsphenamin, this numerically heavy infection should not be the important factor. Nor can it be ascribed to poor blood supply as the parenchyma of the brain is rather richly supplied. Since the vessels commonly display perivascular infiltrations with fibrosis, it may be that the escape of spirocheticides into the parenchyma is hindered. But the more important probabilities are that arsphenamin and its substitutes are not sufficiently lipoid soluble or diffusible in the brain and that mercury does not tend to accumulate to spirocheticidal concentrations as well as it does in connective tissue involvements. Occasionally, however, cases having all the clinical and laboratory signs and symptoms of paresis may respond in a surprising manner, leading to long remissions, with improvement of serological findings. As shown by Solomon and Taft,[23] antisyphilitic treatment of paretics may favorably affect the pathological changes. On the other hand, it would appear that histological changes, identical with those met with in paresis, may exist for years in parts of the brain not concerned with the intellectual functions, designated by the late Dr. Southard as "paresis sine paresi" and indicating the long latent or asymptomatic period which may exist in syphilis of the brain.

Experience has shown, therefore, that not a few cases of neurosyphilis and especially cases of the early meningeal or meningo-vascular types, respond favorably to intensive systemic treatment alone or to a combination of systemic and intraspinal treatment. Spirochetes are destroyed and exudates absorbed with consequent clinical and serological improvement. In not a few instances, however, cases of these kinds in whom we have reason to expect such results, fail to improve and every case must be regarded on its own merits.

It is very important to remember, however, that destroyed nerve cells cannot be replaced with restoration of function. Such is frequently expected in tabes dorsalis, optic atrophy, etc. If cells are simply incapacitated by the pressure of lymphocytes and plasma cells, the absorption of these may result in partial or complete restoration of function, so that some clinical improvement may follow specific treatment in paresis, tabes dorsalis and tabo-paresis. A common mistake, however, is to expect too much of specific therapy. In early asymptomatic involvement complete cures are apparently secured in a goodly percentage of cases, but in symptomatic cases of longer standing, the real and usually only hope is for checking the progress of the infection with relief from symptoms and the improvement of functional capacity for the usual span of life.

Diagnosis of Neurosyphilis in Relation to Specific Therapy.—It is not within the province of this treatise to consider in detail the clinical diagnosis of neurosyphilis; nor am I competent to discuss this broad, intricate and important subject. But I have had sufficient experience to be impressed with the necessity for every physician undertaking the treatment of syphilis to at least acquaint himself with the more important signs and symptoms of neurosyphilis and especially the early signs and symptoms, if he cannot have the aid of a colleague skilled in neurological diagnosis and especially what may be called a sub-speciality in this branch, namely, syphilitic neurology and psychiatry. Naturally, I have had more experience in serological diagnosis already discussed in Chapter XLII, but realize its limitations in both diagnosis and as a control on treatment, as discussed by Sachs,[24] Finlaysen,[25] Fordyce[26] and others.

Probably the most important phase of diagnosis in relation to treatment is the ability to detect the *early* signs and symptoms of neurosyphilis, since so much may be gained by appropriate treatment at this time. The recognition of well-developed paresis or tabes is not usually a difficult matter, but the diagnosis of early involvements is a matter requiring much experience and thorough clinical examination. In asymptomatic cases, examination of the spinal fluid is the only means for diagnosis; in cases presenting mild or indefinite signs and symptoms, these tests are also of great value. During the first two years of syphilis the symptoms may be quite varied as headache, vertigo, insomnia, nervousness, pains in the extremities, phobias, and inability to concentrate. Careful examination may show early optic and auditory involvement with irregular pupils and alterations in the patellar and other deep reflexes the subject having been recently covered in a masterly manner by the late Dr. Fordyce.[27]

Attempts to Increase the Penetration of the Tissues of the Central Nervous System by Spirocheticides.—Owing to the frequency of neural infections and the unsatisfactory status of the treatment of parenchymatous infections, it is not surprising that early and frequent attempts have been made to increase the degree of penetration of spirocheticides in the tissues and spinal fluid during systemic medication. Among the earliest was the method of Sicard and Reilly,[28] consisting in the subdural injection of 5 c.c. of 0.5 per cent. saline or 0.0001 gm. mercury cyanid. Viton[29] thought that the injection of a mixture of this amount of cyanid with 0.015 gm. of novocain in 2 c.c. of saline was helpful in the treatment of tabes. Stillman and Swift,[30] however, claim that the subdural injection of normal salt solution, normal serum, serum arsphenamized *in vivo* or weak solutions of cyanid of mercury do not demonstrably increase the permeability of the spinal cord or brain for arsphenamin circulating in the blood at the time of the subdural injection. But subsequent investigations in syphilis, as well as in poliomyelitis, have shown that intraspinal injections of normal or medicated serum or saline solution does tend to increase extravasation from the vessels of the meninges or excretion by the choroid plexus, as shown by the experiments of Sekiguchi and myself,[31] and others. Shera[32] has recently advocated the intraspinal injection of 20 to 30 c.c. of 40- to 70-per cent. dilutions of the patient's own non-medicated serum for this purpose, but these precedures may also favor infection of these tissues with *Sp. pallida*, which constitutes the reason why most syphilologists are opposed to even simple spinal puncture during the early stages of syphilis until after sufficient treatment has been given to sterilize the blood. But whether or not such measures are worth while in the treatment of neurosyphilis, purely from the standpoint of increasing permeability for arsenic in the blood stream, is another matter. Keidel and

Moore,[33] for example, treated 25 cases of neurosyphilis with 6 weekly intraspinal injections of mercurialized serum (Byrnes method) followed twenty-four hours later by intravenous injections of arsphenamin to obtain maximum concentrations of arsenic in the blood at the time of maximum meningeal irritations, but found the results inferior to the Swift-Ellis method and an indication, in their opinion, that the mode of action of intraspinal medication does not depend upon increased permeability by the production of aseptic meningitis.

In 1916, Gilpin and Earley[34] advocated thorough spinal drainage as a means of favoring penetration of the tissues of the central nervous system during systemic treatment with arsphenamin or mercury by producing sudden reduction of spinal fluid pressure with resulting hyperemia and increased production of fluid; Dercum[35] became an enthusiastic advocate of the method and Finlaysen,[36] Hearn,[37] Schaller and Mehrtens,[38] Craig and Chaney,[39] Harrison[40] and others have observed favorable effects in some cases, but Pilsbury,[41] Fordyce,[42] Stokes and Osborne[43] and others have failed to secure encouraging or satisfactory results and believe the method less satisfactory than the Swift-Ellis method of intraspinal medication. My own experience has been apparently similar to that of Solomon,[44] who found spinal drainage of some value. It is exceedingly difficult, however, to evaluate the results in definite terms and in the final analysis I believe it is inferior to methods employing intraspinal injections of medicated serum, although I believe that spinal drainage as practiced by Dercum may increase permeability for the organic arsenicals in some cases of neurosyphilis.

A promising work along these lines at present is the method of Corbus, O'Connor, Lincoln and Gardner,[45] who gave an intravenous injection of 100 c.c. of a 15-per cent. solution of sodium chlorid; this is followed by an enormous drop in spinal fluid pressure and the patient is kept in bed. About six hours later 0.6 to 0.9 gm. of neoarsphenamin is injected intravenously at a time when the spinal fluid pressure is being restored and a few hours later the patient is allowed to get up. In 26 out of 28 cases of neurosyphilis this was followed by an increase of arsenic in the spinal fluid. The method is based upon the work of Weed and McKibben,[46] who found that hypertonic sodium chlorid solutions given intravenously or solutions of sodium sulphate and sodium chloride administered by rectum lower intracranial tension with consequent pressure changes in the cerebrospinal fluid. Their findings were corroborated by Foley and Putman[47] and the phenomenon has since had practical application in the field of surgery. Fordyce, Rosen and Myers,[48] in an analysis of 76 specimens of cerebrospinal fluid for arsenic at various periods, after the application of this method, found a considerable regularity in the quantity of arsenic penetrating to the cerebrospinal fluid. Only one specimen was found in which it was not present. While there appears to be a uniformity in penetration, they conclude that it would seem from the data thus far collected that this procedure does not favor the passage of large amounts. What may be called the reverse of this mechanism has been attempted by Wynn,[49] who tried the effects of giving an intravenous injection of 200 c.c. of 15 per cent. sodium chlorid solution after intraspinal medication, in order to promote absorption of the drug from the subarachanoid space; the method however, has not yielded encouraging results since some cases were aggravated and others not improved.

But far more effort has been expended in attempts to augment the effects of systemic medication in neurosyphilis, by various methods of intraspinal medication. Before taking up a consideration of this subject, however, it

may be well to express an estimate of the value of systemic medication alone with various spirocheticidal medicaments.

Value of Arsphenamin, Silver Arsphenamin and Neoarsphenamin in the Systemic Treatment of Neurosyphilis.—Both arsphenamin and neoarsphenamin by intravenous injection have been proven to possess a high degree of curative activity in neurosyphilis; silver arsphenamin has been especially recommended by Stewart[50] and others. In the early types they appear sufficient when administered in conjunction with mercury and the iodids. Many physicians are of the opinion that the intravenous injection of arsphenamin is the more curative phase of the Swift-Ellis method; Sachs,[51] Kaliski and Strauss[52] are especially convinced of this and practically all syphilologists are agreed that intraspinal medication should be deferred in any given case until intravenous arsenical treatment associated with mercury by inunction or injection and iodids by ingestion, have been given a thorough trial. It is admitted that large doses are required, as likewise treatment over a long period of time in order to secure therapeutic results.

Arsphenamin is superior to neoarsphenamin in the treatment of neurosyphilis; it appears to possess a higher degree of penetrability for the tissues of the central nervous system and of the two compounds, is the drug of choice. Silver arsphenamin is regarded by some physicians as slightly superior to arsphenamin, but this has not been proved and in my opinion it is neither superior nor to be preferred. Neoarsphenamin is quite sufficient for the treatment of early, spinal fluid or asymptomatic neurosyphilis, but for symptomatic cases, arsphenamin is to be preferred. Sicard,[53] however, claims to have obtained noteworthy results in the treatment of tabes, paresis, syphilitic paraplegia and hemiplegia by the daily administration of neoarsphenamin subcutaneously or intravenously in doses not exceeding 0.15 gm. over an extended period. He has given as much as 50 gm. within a space of two years. He believes this method of treatment to be less dangerous than weekly injections of larger doses and superior in its results in nervous syphilis and in its effect on the Wassermann test in the blood and spinal fluid. He has not observed any nitritoid reactions, but mild erythemas have been observed in 6 to 8 per cent. of cases, benign icterus in about 2 per cent. and progressive diminution of the ankle jerks in about 60 per cent. of cases. Mott[54] mentions this "driblet method" quite favorably, administering the drug in glucose solution by subcutaneous injection. Arata[55] has also rendered a favorable report on the method. As in the treatment of chronic cardiovascular syphilis, it is certain that prolonged administration is required in conjunction with mercury and iodids, for securing a cessation of progressive infection of the tissues and especially of parenchymatous infections.

Value of Sulpharsphenamin and Tryparsamid in the Systemic Treatment of Neurosyphilis.—Considerable interest is being shown at present in sulpharsphenamin and tryparsamid in the treatment of neurosyphilis. Voegthin, Smith, Dyer and Thompson[56] have found that both drugs possess a higher penetrability for the central nervous system than arsphenanim, silver arsphenamin and neoarsphenamin. Tixier and Duval[57] have reported excellent results with small doses of sulfarsenol (starting with 0.06 gm.) by daily subcutaneous injection after Sicard's method described above, when used in conjunction with mercury and iodid. Stokes and Behn[58] have had a particularly favorable experience with sulpharsphenamin in the treatment of neurosyphilis following courses of light weekly intramuscular injections of 0.4 gm. (0.2 gm. in each buttock), and their report warrants a thorough trial of the drug, although it is still too early to express a final opinion of its value and

especially in the treatment of tabes dorsalis and paresis. Just why sulpharsphenamin should have given them exceptionally good results is difficult to state, since the chemistry of the compound does not indicate that it is much different from neoarsphenamin insofar as lipoid solubility is concerned while its spirocheticidal activity is not greatly and indeed, not usually as high. In my opinion, the alleged superior results are probably due to the method of administration, since intramuscular injections are followed by slower absorption and slower elimination, the latter being the chief factor and enabling a better penetration by the longer time afforded for contact with the tissues, which appears to be a matter of great importance in the penetration of the parenchyma of both brain and cord by the organic arsenicals. I do not doubt that, if arsphenamin and neoarsphenamin could be administered in similar doses by subcutaneous or intramuscular injection, their therapeutic properties in neurosyphilis would be greatly enhanced; indeed, this is indicated both by the results of animal experiments and Sicard's success with daily small doses of neoarsphenamin by subcutaneous injection.

Probably the same factors explain the apparently excellent results being reported from intravenous injections of tryparsamid combined with intramuscular injections of mercury, in the treatment of paresis, tabes and other types of chronic neurosyphilis. This compound is very much lower in spirocheticidal activity than arsphenamin, neoarsphenamin or sulpharsphenamin, as shown in Chapter XXIII, but it is likewise less toxic for body cells permitting the intravenous injections of doses as high as 3 gm. once a week or two weeks for courses of ten or more injections. This brings a very large amount of pentavalent arsenic to the tissues at one time with apparently a high degree of penetration, since the compound is eliminated somewhat less rapidly. Aside from this it would appear, from the investigation of Voegtlin and his associates, that pentavalent organic arsenicals possess in high degree the power of penetration of the tissues of the brain and cord, as shown by the results observed in the treatment of trypanosomiasis of the subarachanoid space of rabbits with tryparsamid and the sodium salt of 3-amino-4-oxy-phenol arsonic acid. But it is curious that tryparsamid even in doses as high as 3 gm. for adults, possesses so little spirocheticidal activity in early syphilis that it is very much inferior to arsphenamin, neoarsphenamin and sulpharsphenamin in the treatment of primary and secondary syphilis and early asymptomatic neurosyphilis; its value is confined largely and almost entirely to the treatment of chronic types of neurosyphilis as shown by the reports of Lorenz and his colleagues,[59] Moore, Robinson and Keidel,[60] Hindman,[61] Solomon and Viets,[62] Schaller,[63] Stokes,[64] Cady,[65] Skoog,[66] Read,[67] Neyman,[68] Kennedy and Davis,[69] Wile,[70] Crawford,[71] Vines[11] and others.

Moore and his colleagues have emphasized that the drug should not be used in cases with optic nerve involvement and in a subsequent study by Woods and Moore[73] of 241 patients receiving more than 3000 injections of the compound, dimness of vision was observed in 10.2 per cent. and constriction of the visual fields for form, without scotomas, and with or without diminution in visual acuity, in 5.5 per cent. In their experience they found (1) that 94 per cent. of all reactions occurred early in the course of the treatment, by the time of the tenth injection; (2) that visual disturbances bear no direct relationship, within certain limits, to the dose of the drug administered; (3) that disease of the central nervous system, especially general paralytic and tabetic neurosyphilis, is to some extent a predisposing factor to visual disturbance from tryparsamid; (4) that preexisting syphilitic disease of the optic nerve or retina is not necessarily a contraindication to

the use of tryparsamid; (5) that it is probable that the drug exercises, in some instances, a direct toxic action on the retina or the optic nerve; (6) that before beginning tryparsamid therapy, every patient should be examined by a competent ophthalmologist as to visual acuity, fundi and visual fields. The occurrence of any visual disturbance must form the occasion for a second examination. Lillie,[74] however, in a study of the eyes of 114 cases of syphilis under treatment with tryparsamid, found that ocular changes occurred as often with arsphenamin treatment as with tryparsamid and he is inclined to believe that the changes in vision, fundi and perimetric fields are due rather to syphilis than to the drugs.

It would appear, therefore, that the preliminary reports on tryparsamid in late neurosyphilis and especially paresis, tabes and taboparesis are encouraging; all are agreed, however, that it is too early to express a final opinion since the improved patients must be observed for at least five years to determine the length of the remissions, since no one can assume at present that the cases are actually cured in the sense of complete extirpation of the disease. Tryparsamid is also of value for its roborant and nutritional effects but must be given with great care when eye lesions are present even though these do not absolutely contraindicate the use of the drug. But its employment should be confined to late neurosyphilis as it is inferior to arsphenamin and its substitutes in the treatment of early syphilis and also in late syphilis of organs other than of the central nervous system.

Value of Mercury, Bismuth and the Iodids in the Systemic Treatment of Neurosyphilis.—Of course, mercury has been for ages the chief drug for the treatment of neurosyphilis and at the present time practically all neurologists and psychiatrists advocate its administration along with the organic arsenical compounds. Mercury, however, has not produced any noteworthy results in paresis, although it is not to be overlooked that the remissions of this disease under the older forms of mercurial treatment and sometimes lasting several years, may have been due in part to its therapeutic effects. Mercury, and especially by inunction, is particularly valuable in the treatment of tabes dorsalis, and in my opinion should never be omitted in this disease, especially if treatment can be conducted by inunction after the methods practiced at Aachen abroad and the Hot Springs of America. In early asymptomatic neurosyphilis, dependence should not be placed in mercury alone because it is decidedly inferior in spirocheticidal activity to arsphenamin and its substitutes, but in late neurosyphilis of all types, it deserves a prominent place in treatment and especially by inunction. Just why mercury has failed in paresis is unknown; it is my opinion, however, that the metal is lacking in penetrating properties for the parenchyma of the brain and fails to accumulate in the brain to spirocheticidal concentrations, although it may do so inthe meninges on account of their fibrous structure and therefore prove more valuable in the treatment of meningeal tabes and meningovascular lesions than in parenchymatous infections.

Bismuth is apparently proving more useful than mercury and especially in meningeal types of neurosyphilis with headache. Favorable reports have been rendered by Shivers, Dessert, Hudelo, as well as by Milian,[75] Marie and Fourcade,[76] Tixier,[77] Foster and Smith[78] and others, although it is too early to express a final opinion of the value of bismuth salts in neurosyphilis. I believe, however, that present results justify one using the insoluble compounds by intramuscular injection as a substitute for mercury and especially when injections of the latter are contra-indicated.

The iodids are of most value in chronic or late neurosyphilis for their dissolving and absorbing effects upon syphilitic exudates and fibrous tissue.

For this reason they are especially indicated in tabes dorsalis but probably also possess some value in paresis and other late lesions although there are no special indications for their administration in early asymptomatic neurosyphilis. Oral administration is apparently sufficient for obtaining their beneficial effects, although several reports indicate that intravenous injections of sodium iodid may be especially serviceable in tabes and paresis.

Practical Value of Systemic Treatment Alone in Neurosyphilis.—It is apparent, therefore, that a good deal may be done therapeutically for many neurosyphilitics by systemic medication alone without resorting to spinal drainage, intraspinal or intraventricular medication, etc. This is especially true in early asymptomatic neurosyphilis and in later meningeal and meningovascular types. Gennerich[79] however, resorts to intraspinal medication almost at once and believes that best results are observed when combined intravenous and intraspinal treatment are given without delay, but I believe that Fordyce and his colleagues give systemic medication alone fair trial in the majority of cases of neurosyphilis before resorting to the Swift-Ellis treatment, unless their cases have already had considerable systemic treatment without satisfactory results before coming under their care. Now that sulpharsphenamin and tryparsamid have apparently increased the efficacy of systemic treatment, it would appear especially indicated to first try thorough treatment with the organic arsenicals combined with mercury or bismuth and the iodids, resorting to intraspinal or intraventricular medication only when these fail to arrest the disease.

Intracarotid Injections in the Treatment of Paresis.—In relation to this subject special mention may be made of recent attempts to treat paresis by injecting neoarsphenamin and sulpharsphenamin directly into the carotid artery in the treatment of paresis since it would appear plausible that by this route the drugs would reach the diseased areas more directly and in higher concentration than by other methods of administration. Knauer[80] apparently used this method in 1919 and Endeslin and Justi[81] devised a method for giving the injections directly through the skin without exposure of the artery. Recently Hirsh, Myerson and Halloran[82] have described their technic and experiments along with a preliminary report on the results of approximately 250 injections of sulpharsphenamin and tryparsamid with improvement in some cases and the opinion that the procedure is warranted in the treatment of a larger series of cases.

Intraspinal Treatment of Neurosyphilis.—In view of the generally unsatisfactory results of systemic treatment of paresis with arsphenamin and mercury and the success attending the treatment of tetanus with intraspinal injections of antitetanus serum and epidemic cerebrospinal meningitis by intraspinal injections of antimeningococcus serum, it is not surprising that early and persistent attempts were made to improve the treatment of neurosyphilis by introducing spirocheticidal substances directly into the spinal fluid with the hope that they would not only reach spirochetes in the meninges but likewise those organisms entrenched in the deeper portions of the brain and cord. The first attempts in this field were made by Marinesco[83] in 1911 followed independently and almost simultaneously by Swift and Ellis[84] and Wechselmann.[85] Since then many different methods have been advocated and a large literature accumulated, most of which is of a controversial and confusing character on the merits or demerits of this or that method or on the subject of intraspinal *versus* systemic treatment in general. Before, however, taking up the questions of the practical value of intraspinal treatment in general, the indications, contraindications and probably mechanism of curative or beneficial activity, I shall briefly review the status of various agents employed and of methods for their administration.

Subarachanoid Injections of Neoarsphenamin in the Treatment of Neurosyphilis.—Wechselmann was the first to inject dilute solutions of neoarsphena-

min intraspinally and the method received enthusiastic support from Ravaut[86] in Europe and Wile[87] in America. As a general rule, from 0.0005 to 0.005 gm. were injected, but it was not long before the method received unfavorable mention by reason of numerous and sometimes serious evidences of meningeal and cord irritations. Schubert[88] then devised a plan for dissolving 0.045 gm. of neoarsphenamin in 3 c.c. of spinal fluid and mixing 0.1 or 0.2 c.c. with 5 c.c. of fluid which had been allowed to flow into a funnel attached to the lumbar puncture needle. This method undoubtedly reduced the incidence and severity of cord and meningeal irritations and the principle has since been adopted for the Swift-Ellis and Olgilvie methods; Gennerich[89] especially found the method superior to neoarsphenamin dissolved in water or saline solution. But at the present time methods of these kinds are not generally employed because of the reports by Corbus,[90] Gordon,[91] Sachs, Strauss and Kaliski[92] and others indicating that severe local reactions may occur. The milder form of these consist of urinary retention, and incontinence, rectal paralysis, parethesias and numbness of the buttocks and legs, ataxia in the legs, girdle pains, trophic ulcers, and in severe cases complete paralyses and death. If given at all, the dose should not be more than 0.0005 gm. in spinal fluid; arsphenamin is so much more irritating that its use by this method is altogether out of the question unless the dose is much smaller.

Subarachanoid Injections of Serum Arsphenamized and Neoarsphenamized in Vivo and in Vitro in the Treatment of Neurosyphilis; the Swift-Ellis and Ogilvie Methods.—In order to prevent this irritation of the meninges and cord by the medicament, Swift and Ellis devised their method of arsphenamizing the serum *in vivo* by injecting arsphenamin intravenously and drawing off 40 to 50 c.c. of blood about one hour later from which the serum was secured. Since then the method has been slightly modified in that the blood is drawn off one half hour after injection and the serum mixed with spinal fluid allowed to flow into the barrel of a syringe attached to the spinal puncture needle, as described on page 858, before injection. It is the one method that has stood numerous attacks upon intraspinal therapy in general and undoubtedly is the best and safest method in use today for *repeated* intraspinal injections. Marie and Levaditi[93] have suggested injecting arsphenamin into the lower animals and using their serum, but the method is mentioned only to be condemned since the serum is in no wise less irritating, produces allergic sensitization and denies the patient the very considerable benefit of the intravenous injection, which constitutes in no small degree the value of the Swift-Ellis method.

Ogilvie,[94] however, soon suggested a useful modification to meet the objection of uncertain dosage of arsphenamin in the Swift-Ellis serum, by adding arsphenamin to the serum *in vitro* followed by heating, etc., as described on page 872. It was soon found however, by Draper[95] and others, that the serum sometimes produced irritation, and Fordyce[96] warned against using more than 0.0005 gm. as a dose. Marinesco and Minea[97] then advocated a method of adding 0.006 to as much as 0.012 gm. of neoarsphenamin to serum *in vitro*, but subsequent investigators found these amounts too irritating so that not more than 0.0005 to 0.001 gm. is employed at present. In my opinion the addition of arsphenamin or neoarsphenamin to serum *in vitro* aids in increasing its curative activity and, I believe, that a combination of the Swift-Ellis and Ogilvie-Marinesco-Minea methods is always worthy of trial, to be abandoned, however, in favor of the straight Swift-Ellis method if even minor signs of irritation develop. But the dose of arsphenamin in alkalinized solution to be added to serum should not exceed 0.0005 gm. and the dose of neoarsphenamin should not ordinarily exceed 0.001 gm. in the

interest of safety and especially if a series of injections are to be given. During the past three years I have injected 0.9 gm. neoarsphenamin intravenously, drawing blood a few minutes later and adding 0.001 gm. of neoarsphenamin to the serum, as described on page 872.

Subarachanoid Injections of Mercury and Mercurialized Serum in the Treatment of Neurosyphilis.—I have already mentioned Sicard's method of injecting 0.1 mg. of mercuric cyanid, but this plan has long since been abandoned as likewise Horsley's[98] subarachanoid lavage with mercuric chlorid. Byrnes,[99] however, has suggested a much more useful method consisting of an albuminate of mercury prepared by mixing 1.3 to 2.6 mg. of mercuric chlorid with 12 c.c. of human serum (not necessarily the patient's own), adding 18 c.c. of normal saline and heating at 56°C. as described on page 890. Horse serum should not be employed because of allergic sensitization. When the serum is mixed with spinal fluid before injection, it produces none or but slightly more irritation than observed in the Olgivie method and has been favorably reported upon by Hunt,[100] Haller,[101] Nicholson[102] and others from this standpoint as well as because of greater ease of preparing and preserving the serum as compared with arsphenaminized or neoarsphenaminized serum, whereas Hazen[103] and others state that too much irritation is produced.

Routes of Subarachanoid Injection in the Treatment of Neurosyphilis.—In Chapter LXI, I have described three routes of injection: intraspinal, intraventricular and intracisternal, and this phase of the subject has not received by any means the attention it deserves. Owing to the greater ease of intraspinal injections (lumbar region), this method has become the most popular and widely employed.

In 1914, Berriet[103] injected arsphenamized serum through the sphenoidal fissure into the large basal subarachanoid cistern and recently McCusker,[104] Ebaugh[105] and others have advocated injections of arsphenamized or neoarsphenamized serum into the cisterna magna by Ayer's technic. It is stated that by this route the serum is brought nearer to the seat of cerebral syphilis, that it is just as safe and free of reactions as intraspinal injections and more practical than intraventricular injections.

The latter was apparently first practiced by Ballance[106] in 1914, who injected as much as 90 c.c. of arsphenamized serum into the lateral ventricles by passing a blunt trocar and cannula through a trephine opening and the cerebral cortex. Since then Hammond, Sharpe and Smith,[107] Knapp,[108] and Riggs[109] have described methods and apparently encouraging results in the treatment of paresis.

The use of lumbar puncture is based largely upon the assumption that serum injected in this locality is quickly diffused upward over the upper cord and cerebrum, as observed in the experiments of Dandy and Blackfan[110] with phenolsulphonephthalein, India ink and dyes. But from my experiments with rabbits, I very much doubt if diffusion occurs to the extent indicated by these investigations. Insofar as lumbar injections of serum colored with dyes are concerned, the injection of rabbits with 0.5 c.c. per 1500 grams of weight have almost never shown macroscopic evidences of diffusion above the level of the medulla whereas intracistern injections have shown diffusion downward and over the base of the brain while injections into either of the lateral ventricles have shown intense staining of both hemispheres of cerebrum, the base and diffusion downward as far as the upper third of the cord. Indeed, I have been so much impressed with the uniformity of these results that I suspect that the failure of intraspinal medication in the treatment of basilar meningitis and especially of paresis, is largely due to failure of

diffusion from the lumbar region to these structures whereas in early tabes excellent results have been observed because of the readiness of contact with the areas of meningitis involving the posterior roots and ganglia of the sensory nerves. I surmise that Solomon[111] is very much of the same opinion and I believe that intracistern and intraventricular medication are deserving of more serious attention and use in the treatment of paresis than they have had in the past, although with less serious types of neurosyphilis intraspinal medication apparently suffices.

Practical Value, Indications and Contra-indications of Subarachanoid Medication in Neurosyphilis.—It is hardly profitable for me to review here in detail the large literature upon this subject, as I believe it has been covered by the frank and complete discussion by Fordyce,[112] who recently reviewed his experience of the past ten years with special reference to the value, indications and contra-indications of the Swift-Ellis method.

Possibly Fordyce has ascribed more benefit to the intraspinal than to the intravenous phase of the Swift-Ellis method; at least the opponents of the method are of this opinion and there can be no doubt of the value of systemic treatment alone, but when the latter has been tried and failed to at least arrest the progress of infection, I believe it is our duty to employ intraspinal medication unless there are distinct contra-indications. The latter, in my practice, have been present more in cases of tabes than in paresis or other forms of neurosyphilis, in the form of rectal and bladder disturbances which are so easily intensified by lower cord irritation. When in doubt about the wisdom of employing intraspinal medication in cases in whom it is particularly imperative to minimize all meningeal and cord irritation, I believe the Swift-Ellis method is by all odds the method of choice; certainly we should avoid overdosage and injurious reactions as emphasized by Fuchs[113] and others.

Mechanism of Therapeutic Activity of Subarachanoid Medication in Neurosyphilis.—If benefits are to be ascribed to subarachanoid medication, how are they to be explained? Failure to provide an acceptable explanation of the mechanism has alone brought undeserved criticism of the Swift-Ellis method.

That some medicament is contained in the serum taken from blood drawn within half an hour after the intravenous injection of 0.6 gm. arsphenamin or 0.9 gm. of neoarsphenamin is certain, even though the results of analyses in terms of metallic arsenic have shown only traces with a portion retained in the clots. The fact that the serum increases in spirocheticidal activity as a result of heating at 55°C. before injection strongly suggests that this is due to oxidation of the arsphenamin or neoarsphenamin with the production of the highly spirocheticidal trivalent oxids of which "arsenoxid" is the best known; at least I am unable to offer any other explanation for the phenomenon, which appears to occur as a result of heating the serum. But is the amount present sufficient for spirocheticidal activity and especially when it is remembered that the serum is still further diluted by the cerebrospinal fluid after injection? Swift and Ellis[114] claim to have demonstrated the spirocheticidal activity of the serum *in vitro* and Stuhmer[115] states that it has a similar action on trypanosomes. Unfortunately my own experiments have not yielded conclusive results. I have repeatedly mixed equal parts of a saline-rabbit-testicular-syphiloma-tissue suspension of virulent *Sp. pallida* with patient's serum drawn immediately before, one half and one hour after intravenous injections of arsphenamin and neoarsphenamin, at 37°C. for intervals from five to fifteen minutes, followed by intratesticular inoculation of rabbits, as a test for spirocheticidal activity, with the result that the mixtures with serum drawn before injection were sometimes non-infectious when the mixtures with serums drawn after injection were not, indicating an apparently enhanced spirocheticidal activity of the Swift-Ellis serums. However, the serums before and after injection were both spirocheticidal in some tests while in other tests they were not; in other words *Sp. pallida* is rather easily destroyed at 37°C. in fifteen minutes and the results were sufficiently irregular to prevent definite conclusions, but, in general terms, the results tend to confirm Swift's claims for increased spirocheticidal activity. Numerous experiments *in vitro* with saline

suspensions of cultures of *Sp. pallida* have indicated in a general manner that concentrations of arsphenamin in the neighborhood of 1:500 to 1:1000 are required for the almost immediate destruction of the parasites, whereas in long contact over days or weeks concentrations of arsphenamin about 1:8000 and neoarsphenamin about 1:3000 are required, as discussed in Chapter XXVIII. It is certain that the concentrations in the Swift-Ellis serum are not ordinarily this high. Probably a dose of 0.6 gm. of arsphenamin per 70 kilograms of weight gives a dilution of not less than 1:10,000 when the volume of blood and other body fluids as well as rapid fixation by the organs, are taken into consideration. But when one recollects the wonderful and prompt disappearance of spirochetes from a chancre following the intravenous injection of 0.010 gm. of arsphenamin per kilogram of weight of either human being or rabbit, and what a high dilution this represents in the blood and lymph, I believe that most will agree with me that it is impossible to accurately correlate the results of spirocheticidal activity *in vivo* and *in vitro* and especially since so many other factors require consideration in the former. Therefore, while Swift-Ellis serum may be sufficiently spirocheticidal in the subarachanoid space, there are reasons for being much surer of this when 0.0005 gm. of arsphenamin or 0.001 gm. of neoarsphenamin are added *in vitro*, as in Ogilivie's and my methods, although the total amounts are still below what the results of *in vitro* spirocheticidal tests would lead one to expect as required for spirocheticidal effects in the subarachanoid space after dilution with 50 to 150 c.c. of cerebrospinal fluid. Certainly not all or even a goodly proportion of the beneficial results, are to be ascribed to this one factor; other agencies must be concerned.

Very probably considerable benefit accrues from the passage of the medicament from the blood into the tissues of the central nervous system and especially when it is held in relatively prolonged contact with them by intramuscular injection or intravenous injection over prolonged periods. Furthermore, I believe it is settled as an established fact that in the majority of cases of neurosyphilis, traces of the arsenicals reach the spinal fluid after intravenous injection, probably even in spirocheticidal concentrations in some cases, from which a degree of therapeutic effect is to be expected and especially in meningeal, vascular and meningo-vascular infections. Furthermore, that which has passed into the spinal fluid is again absorbed with possible spirocheticidal effects in passage, since absorption of the organic arsenicals introduced directly into the subarachanoid space is shown by the production of dermatitis, etc., as reported by Schönfield[116] with silver arsphenamin, in the course of a very interesting series of experiments upon the permeability of the choroid flexus and meningitis for argoflavin, indigocarmin, uranin and methylene-blue. When medicated serum is injected into the subarachanoid space, it is almost certain that a reaction follows of which increased congestion of the pia and possibly slight cellular and serous exudation are the chief changes; these alone are probably of therapeutic benefit, purely from the standpoint of a non-specific reaction to be discussed shortly, even though it were granted that they do not increase the penetration of spirocheticides present in the blood stream, which I believe actually occurs in some cases. It may be that the results of intraspinal treatment with the Ogilvie method, in which intravenous injections are not given, are as good as in the Swift-Ellis method in which intravenous injections are given, in which case the question of the importance of increased permeation of drugs from the blood is minimized. This is true, insofar as intravenous injections of arsphenamin are concerned in immediate relation with the technic, but examination of published records show that most cases treated by the Olgivie method have been under mercury or arsphenamin treatment at the same time, in which case the intraspinal injections may still encourage passage of the drugs into the tissues of the brain and spinal cord and especially mercury which is not eliminated as rapidly as the organic arsenicals.

Is a part of the curative effect of Swift-Ellis serum due to the presence of antibodies? I doubt that such is the case. The serum does not contain complement, because this is destroyed during the process of heating, although

following the injection, it is highly probable that complement from the patient's own blood reaches the spinal fluid as a result of the aseptic irritation and indeed, in cases of paresis at least, may be already in the spinal fluid along with natural antisheep hemolysin, as a result of increased permeability of the meninges in this disease (Weil-Kafka reaction). It is probable that the serum of the patient may contain small amounts of spirocheticidal substances, as indicated by the results of Eberson's[117] experiments, although the experiments of Broadwell and myself[118] yielded negative results with cultures of *Sp. pallida*. But granting that minute amounts of specific antibodies are present, and more cannot be granted, it is highly probable that after dilution with spinal fluid they play no important part in curative activity and especially since equally good results have been observed when the serum of perfectly normal non-syphilitic individuals have been substituted for patient's serum.

Probably an important effect of subarachanoid medication in neurosyphilis is to be ascribed to a non-specific protein reaction. It is true that if such occurs, the reaction must be mild in view of the fact that temperature and leukocytic changes do not occur at all or but to a slight degree. But the therapeutic activity of auto- and homo-serum therapy has been observed so frequently in the treatment of disease and especially of various diseases of the skin, that it is not unreasonable to assign a goodly proportion of the beneficial effects of subarachanoid therapy with plain or medicated human serum to this category and especially since it has been shown that the administration of non-specific protein agents has favorably influenced other chronic syphilitic lesions, as discussed in Chapter LXVIII. Indeed, as I shall shortly review, the subcutaneous or intramuscular injection of tuberculin, various vaccines, milk, etc., are reported to favorably influence neurosyphilis and it may be expected that subarachanoid injections of serum may have the same effects since absorption is rapid, yielding mild systemic reactions in addition to the far more important local reaction of which one important phase is hyperemia, duplicating in this respect the curative activity assigned to Bier's hyperemic treatment of chronic infections. It is not surprising, therefore, that Swift[119] and others have found that intraspinal injections of normal serum were beneficial even though it may not be granted that they increase the permeability of the choroid-meningeal complex for spirocheticides in the blood.

Nor can definite statements be made at this time of the mechanism of curative activity concerned in such non-specific reactions. Doubtless the increased congestion and positive polymorphonuclear leukocyte chemotaxis bring out in maximum degree the antispirochetic properties of the blood and may stimulate the tissues in contact with the spirochetes to produce increased amounts of specific anti-spirochetic substances, since we may accept as proven that the tissues in contact with *Sp. pallida* are constantly offering resistance which is frequently sufficient for holding the parasites in check or latency. Indeed, Gooken[120] has advocated injecting intravenously the spinal fluid removed in the course of intraspinal medication, with the idea in mind of giving the patient the benefit of any antibodies contained in the fluid, but unfortunately our information on the subject of antibodies in syphilis is so meager at present that one cannot discuss this phase of the subject with assurance, except to state that in all probability the antibody concerned in the Wassermann reaction is not in itself anti-spirocheticidal.

Before taking up the further discussion of non-specific protein therapy in the treatment of neurosyphilis, I believe that the mechanism of subarachanoid therapy may be summarized as follows, the relative importance of the various agencies being arranged in this order: (1) The non-specific effects

due to subarachanoid irritation following the injection of plain or medicated human serum from the patient or some other human being; this, in my opinion, is the most important reaction of all. (2) The increased penetration of the tissues by spirocheticides in the blood, as the result of disturbances of the choroid-meningeal complex due to spinal drainage and intraspinal injections. (3) The spirocheticidal activity of medicaments in the serum and (4) possibly, the influence of specific anti-spirochetic antibodies when autoserum medication is employed, as in the Swift-Ellis method. In order to secure the operation of all these agencies, I believe that subarachanoid medication is best conducted by a method combining the Swift-Ellis-Ogilvie methods, as my own does, being careful, however, not to add ordinarily more than 0.001 gm. of neoarsphenamin or arsphenamin to the serum *in vitro* in order to avoid too much meningeal and cord reaction with temporary motor and sensory disturbances.

Non-specific Protein Treatment of Neurosyphilis.—If the benefits following subarachanoid medication in neurosyphilis with plain or medicated serums are partly due to local and systemic non-specific reactions, which I believe are important agencies concerned in the therapeutic mechanism, of what value are subcutaneous or intramuscular injections of other protein agents, as milk and vaccines? I have already discussed the subject of non-specific protein therapy in the general treatment of syphilis in Chapter LXVIII, but it is so important in relation to the treatment of neurosyphilis, that additional mention of it would appear warranted.

Since Marro,[121] v. Halban[122] and numerous other clinicians had noted the apparent beneficial effects of malaria, typhoid fever, erysipelas, etc., upon the course of paresis, the idea gained ground that the production of acute fever by other agents may be beneficial in the treatment of paresis and tabes, since no one at that time had the temerity to produce infection for this purpose, as V. Jauregg-Wagner finally did some years later by inoculating with tertian malarial parasites, although Meyer[123] in 1877 had advocated the production of abscesses for this purpose.

On this basis V. Wagner[124] began using subcutaneous injections of pyocyaneus vaccine and then Koch's old tuberculin with encouraging results Pilcz[125] continued his work with tuberculin, starting treatment with 0.01 gm. and continuing up to 0.5 gm. and in 1911 reported that of a series of 86 cases of paresis treated in this manner, along with mercury and the iodids, about 60 per cent. showed improvement with marked relapses in 26 per cent.

At about the same time, Fisher[126] and Donath[127] began using subcutaneous injections of sodium nucleinate in doses of 0.5 gm. to as much as 3 gms. at weekly intervals along with the administration of mercury and iodid in the treatment of paresis, the latter reporting marked improvement in 47 per cent. of cases. Hauber,[128] Szedlak[129] and others followed with favorable reports on combined treatment of paresis with nuclein and mercury and Schacherl[130] in the treatment of tabes with subcutaneous injections of 0.001 gm. of tuberculin and salicylate of mercury, but Hussels,[131] Plange,[132] Lowenstein,[123] Kleinberger,[134] Bowman,[135] Friedländer,[136] Plaut[137] and others have claimed negative results and even harmful reactions in some instances from injections of tuberculin, nuclein, typhoid vaccine by intravenous injection, staphylococcus and streptococcus vaccines, etc.

More recently, however, interest in this subject has been renewed by the observations of Müller,[138] Roper,[139] Fischer,[140] Starcke,[141] Ahlswede[142] and others indicating that intramuscular injections of sterile milk, "aolan," "pylogetan," etc., are of value, along with specific therapy, in the treatment of paresis, tabes and other types of neurosyphilis although it is very difficult to properly evaluate the results by reviewing their accounts, because mercury or arsphenamin were usually given at the same time. Marie and Cohen[143] have reported the results observed with more than ninety general paralysis cases in which bismuth associated with shock treatment was followed by pronounced remissions in over 50 per cent. while the mortality was much less than in control groups. Of the three forms of what they call "leukopyretotherapy" tested (parenteral injections of milk, sodium nucleinate, or tuberculin), tuberuclin proved the most effectual. The bismuth was injected the day following the tuberculin; the dose of the latter was regulated to induce fever and leukocytosis without too much reaction. From ten to twelve of these therapeutic shocks were generally given, at three or four day intervals as a rule. Enough work has been done to indicate that the fever, leukocytosis and possibly an increase in serum proteases and lipases, believed to follow the administration of so-called non-specific agents, may be distinctly

helpful in the treatment of paresis and tabes and especially when administered along with arsphenamin, bismuth, etc. Care must be exercised in the selection of patients and in dosage in order to produce slight fever with increase of blood leukocytes and platelets and the amount to inject as well as the length of intervals between injections, varies with individual cases and the agent employed. Care must be also exercised in avoiding too many reactions in order not to produce "proteinogenous tiring" and "proteinogenous cachexia." In my experience the weekly intramuscular injection of 4 to 6 c.c. of market milk, boiled for ten minutes and cooled, or 5 c.c. of the various commercial preparations of milk or milk proteins, for 6 to 8 injections, ordinarily suffice as a course of non-specific treatment in conjunction with mercury by inunction, iodids by ingestion and arsphenamin, neoarsphenamin, tryparsamid or bismuth by injection. If tryparsamid is employed, auxiliary injections of such proteins are not required because this drug frequently improves the nutrition in a remarkable manner with a gain in weight and improvement of anemic states.

Just how non-specific protein therapy may improve the treatment of paresis and tabes cannot be stated. Probably such vascular changes as hyperemia and increased capillary permeability, which are believed to be produced by these agents, aids in the penetration of syphilitic tissues by specific spirocheticides, and for this reason I believe that arsphenamin or one of its substitutes, mercury or bismuth, should be always administered along with or immediately following the protein agent. Probably the fever and leukocytosis are in some manner beneficial and especially since the inoculation of paretics with the plasmodia of tertian malaria is claimed to constitute a valuable treatment for paresis, which subject may now receive discussion.

Treatment of Neurosyphilis with Special Reference to Paresis by Infection with Malaria and Relapsing Fever.—At the present writing the treatment of neurosyphilis and especially paresis, by inoculation with tertian malaria or *Sp. recurrentis* (African relapsing fever) is the most important subject in this field and is attracting great attention and favorable comment in Europe and particularly in Germany and Austria. The method has also been tried in Sweden and England, but to a lesser extent in France and America.

As mentioned in the preceding section there are numerous references in the literature bearing upon the apparent benefits accruing to the syphilitic from intercurrent febrile infections. In addition to those cited above, Olgivie mentions that Baillarger, in 1849, reported a remarkable remission in a paretic following a series of furuncles; also that Nash, in 1870, reported the "recovery" of a case following an attack of small-pox and that Fritsch and Buss, in 1884, reported remissions following erysipelas and sloughing infections.

These observations, however, did not attract much attention until V. Jauregg-Wagner[144] suggested in 1918, a possible means of improving the method of treating paresis with injections of tuberculin and nuclein, by inoculating with malaria, believing that the disease was of such a fatal character that any procedure not in itself dangerous, was justifiable in an effort to check its progress and terrors. Muhlens, Weygandt, and Kirschbaum[145] took up the subject by treating a series of 33 cases with inoculations with the *Sp. obermeiereri* and malaria plasmodia; of these four died (but not directly from infection), twelve improved and five did not improve, the remaining twelve being under observation for too brief a time to report upon. Pagniez[146] also reported favorable results and the review by Raecke[147] appeared to establish the method as meriting a thorough trial. Since then numerous reports have appeared, the majority of writers being of the opinion that a distinct advance has been made in the treatment of paresis.

Choice of Infection.—The majority of investigators have employed inoculation with *tertian malaria;* a few have employed the spirillum of relapsing fever (*Sp. obermeieri*).

The former is preferred because much easier of cure when a sufficient number of paroxysms have occurred and the results appear to have been more pronounced and satisfactory as reported by Weichbrodt,[148] Weygandt[149] and others. Due care must be taken, however, against the inoculation of paretics hyperesensitive to quinin and it is well to apply a skin test or better still, to administer 5 grains of quinin as a test before deciding upon malarial therapy.

Great care must be exercised in the selection of a strain of malaria plasmodium, since infections with aestivo-autumnal parasites (tropical malaria) have proved fatal, as stated by Muehlens[150] and Plehn;[151] Marinesco and Draganescu[152] have recorded a fatal *plasmodium vivax* infection in a case of paresis activated by injections of arsphenamin. Wagner and others have shown that the experimental asexual tertian infections are much easier to cure with quinin than natural infections resulting from anopheles transmission and while a few investigators have reported remissions of the malaria, no particular difficulties in the cure of this infection have been reported.

Technic of Inoculation.—The malarial inoculations have been made by injecting patients subcutaneously with 1 to 4 c.c. of blood drawn from a malarial patient during or soon after a febrile attack. As a general rule, the strain is maintained by the successive inoculation of paretics and the treatment, therefore, is especially applicable for psychiatric or other institutions in which transmission can be maintained. Since the organisms cannot be successfully cultivated fresh blood should be obtained from an individual carrying the parasites but if obtained from a case of natural or mosquito infection, great care must be exercised to avoid quartan and aestivo-autumnal inoculations. It is far better to obtain blood from a paretic case if at all possible.

The patients must be carefully screened against mosquitoes and especially if anopheles are present in the locality, in order to guard against accidental transmission of malaria, although, as a matter of fact, it would appear from recent experiments in Europe, that the inoculated disease is not transmitted by anophelines as is the natural disease.

As a general rule, there is an incubation period of 10 to 16 days following subcutaneous inoculation before paroxysms develop; when the inoculation is made by intravenous injection, the incubation period is ordinarily about 4 to 8 days. About 10 per cent. of patients do not "take" on the first inoculation and must be re-injected.

The inoculation should be given only to individuals in the early stages of paresis in good general condition; advanced cases do not fare well on account of the debilitating effects of the 10 or more paroxysms required for success.

The same method may be employed for the transmission of relapsing fever or the strain may be maintained by inoculating mice and using saline emulsions of the brain for the subcutaneous inoculation of paretics, when the mice show large numbers of parasites in the peripheral blood. The ease of maintaining a strain in mice is a point distinctly in favor of this infection, but as stated above, the results do not appear to be as good as with malaria and more difficulty has been exercised in curing the infection with arsphenamin than in the cure of tertian malaria with quinin. When relapsing fever therapy is employed, it is necessary to guard against the possible accidental transmission of the disease by lice and bed-bugs.

Duration of Infection.—Most investigators have allowed their patients to have 8 to 15 paroxysms of malaria, but it is advisable to make daily examinations of the blood and interrupt the infection by the intramuscular or subcutaneous injection of quinin, if the malaria becomes too severe. Further indications for immediate discontinuation are sudden loss of strength, pronounced icterus and cardiac weakness.

Many different methods for curing the malaria have been advocated, as the intramuscular or subcutaneous injection of 1 gm. (15 grains) of quinin dihydrochlorid, quinin and urea hydrochlorid or quinin urethan, daily, for two or three days followed by 0.5 gm. on the fourth and sixth days; these are followed by 5 grains of quinin bisulphat daily for a week and these in turn by six to nine weekly intravenous injections of neoarsphenamin. Askgaard[153] gives 0.25 gm. of quinin by injection three times a day for 4 days; this is followed in order by 2 days interval, quinin for 10 days, an interval of one month, quinin for 3 days, an interval of 2 months, quinin for 3 days, an interval of 3 months and finally quinin for 3 days. Great care, however, must be taken to insure complete cure of the malarial infection; Kogerer[154] states that at the Vienna Psychiatric Institute, after tests of the blood had been negative following treatment of the induced malaria by quinin and neoarsphenamin, the blood is examined after roentgen irradiation of the spleen. Later, the use of injections of sodium nucleinate, 5 c.c. of a 10-per cent. solution, was found to be more efficacious for provoking latent malaria. In a series of 25 patients, 3 gave positive blood smears after this injection, and continued treatment of the experimental malaria was instituted. Muchlens states that patients should not leave the hospital until they have been free from parasites for at least three or four weeks and that those inoculated with relapsing fever should remain under observation for at least a month after the last attack. *As a general rule however, cure is easily effected.*

Relapsing fever therapy has been ordinarily allowed to run for periods of four months to two years; Sagel[155] reports one case under treatment for fifty months. The infection may be cured by the administration of arsphenamin or neoarsphenamin, as described in Chapter XXXI.

Indications for Malarial Therapy.—Most success has been observed in paresis and especially early cases. Even in advanced maniacal cases remissions have been produced, as I shall mention shortly in a brief review of the literature. The treatment has also been used in other types of neurosyphilis and especially in tabes dorsalis and some clinicians in Germany and Austria are so impressed with the success and safety of malarial therapy, that they are using it in early asymptomatic cases as a prophylactic measure.

Contra-indications and Dangers of Malarial Therapy.—When due care is exercised in the selection of patients and the malarial parasite (tertian only to be employed), the method is regarded as almost devoid of danger unless the patient is elderly and very debilitated; Loewenfeld regards cases of aortitis as poor risks. Quartan and aestivo-autumnal infections have proven very difficult to terminate and some have ended fatally. Too severe paroxysms should always be checked by quinin. It may be that the malarial attacks increase the danger of toxic reactions from arsphenamin, neoarsphenamin or their substitutes sometimes administered after the malarial infection has been terminated. I know of three fatalities following the administration of neoarsphenamin to paretics subjected to malarial therapy. It is known that malaria alters the usual pathological changes in paresis and I surmise may particularly alter the vascular changes and increase the vasculotoxicity of the arsenicals.

Combination Malarial and Chemotherapy of Paresis.—This naturally brings up the question of the dangers and advantages of combining malarial with the usual therapy of neurosyphilis. As I shall point out shortly the clinical results in malarial therapy have been more striking than the effects upon the Wassermann reaction and spinal fluid changes, although these may undergo improvement at the same time. But Scherber[156] and Scherber and Albrecht[157] believe that best results are secured by combining malarial with treatment by arsphenamin and its derivatives and mercury; at least the serological results appear to be better. But if much treatment is given I believe it well to guard the dosage carefully and when the arsenicals are given after a series of malarial paroxysms, it is advisable to begin with small doses and gradually increase.

Results Observed in the Treatment of Paresis and Other Types of Neurosyphilis.—Pilcz,[158] reporting on malarial therapy in 141 cases of paresis, states that 51 cases completely recovered; 18 showed marked and persisting remission without being able, however, to return to their former occupations, and 57 cases became stationary or showed an incomplete remission. Fifteen patients died but not of malarial infection. He points out that there is no parallelism in the degree and duration of the remissions, on the one hand, and in the serologic reactions, on the other. The best results are obtained in cases with maniacal symptoms and in cases of simple dementia; the hypochondriacal, presenile and catatonic forms of disease show a less favorable prognosis. Generally, remission does not immediately follow treatment; it develops gradually, finally becoming permanent. He states that the method is efficacious not only in cases of paresis, but also in tabes and other forms of neurosyphilis and that in disseminated sclerosis, also good results have been obtained.

Gerstmann[159] has reported that of 304 cases of paresis subjected to malarial therapy, 90 were not influenced, 102 had remissions of varying degree and duration while 112 were able to resume work although minor psychic signs were present. He states that the remissions did not begin ordinarily for several weeks after inoculation. No effect was noted upon the serology of the blood and spinal fluid. In some cases a marked change in the disease was observed and especially a change into peculiar paranoid forms with persecutory delusions and hallucinations of hearing.

Templeton[160] in a review of 296 cases of paresis subjected to malarial therapy, states that complete remissions occured in 112, although the duration of these is not stated in all cases; Grant[161] reports that the therapy was beneficial in all of a series of 40 cases. McAlister[162] states that of 9 cases under prolonged treatment and observation 2 were very much improved, 4

slightly and 3 not at all. Worster-Drought and Beccle[163] report that of 14 paretics subjected to malarial treatment, eleven being early, two advanced and one juvenile, 2 improved sufficiently to resume work, 4 had a definite remission and 8 only a slight remission or none at all. Grant and Silverton[164] state that in all of a series of 40 cases, improvement occurred in the serology of the serum, spinal fluid or both.

Plehn[165] reports that in at least one third of a series of 41 cases treated with malaria, an improvement of the mental psychic condition occurred although improvement of the somatic changes (pupils) was rare. No beneficial effects were observed however, in cases of tabes or other types of neurosyphilis. Additional reports have been made by MacBride and Templeton,[166] Graf,[167] Berger and Untersteiner,[168] Plehm,[169] Bunker and Kirby,[170] MacBride and Carmichael,[171] Grant,[172] Sagel,[173] and Herrmann.[174]

Fewer reports have been rendered on the results of relapsing fever therapy. Sagel[175] states that 11 out of a series of 17 cases of paresis were considerably improved. Weimer[176] reports that in a series of 9 cases of paresis and taboparesis, some improvement in psychic symptoms and serology occurred in the majority and certainly more than commonly observed under arsphenamin therapy alone and Artwinski[177] states that of 17 early cases, remissions have been produced in ten with improvement in the spinal fluid changes in five.

Of course it is not yet possible to express a definite opinion of the results, since more time is required for the final evaluation of these methods according to the duration of the remissions and their degree of symptomatic relief. Many of the German writers have used the word "cure" rather freely, but I believe this should be applied only in a relative sense to designate symptomatic improvement to the extent of restoration of working capacity, and not in the sense of complete extirpation of the infection. Even among those regarded as "cured" some psychic stigmata have usually persisted rendering a return of these patients to positions of responsibility hazardous and inadvisable. But it would appear that malarial (tertian) therapy in *early* cases of paresis is yielding promising results since about 30 to 40 per cent. make clinical recoveries while 20 to 30 per cent. additional show distinct improvement; this is especially true of types of characterized by excitement and expansive ideas as also cases exhibiting dementia and depression. The galloping juvenile and infantile types are not much benefited. Relapses after improvement appear to occur in at least 10 per cent. of cases and these may be safely re-inoculated with malaria. But these results are not any better, and, indeed, not quite as good, as those recently reported in this country by Lorenz, Moore and others, following treatment with tryparsamid. For this reason I doubt if malarial therapy will be adopted in America as enthusiastically as abroad and especially if the results already observed with tryparsamid receive corroboration by further experience.

Mechanism of Malarial Therapy of Paresis.—The mechanism by which malarial and relapsing fever infections produce remissions in paresis has been a subject of considerable speculation. As previously stated, the basis for investigating the effects of malaria by V. Jauregg-Wagner appears to have been the beneficial effects of the fever, which he had produced previously with injections of tuberculin and sodium nucleinate. In this connection it is interesting to note that Weichbrodt and Jahnel[178] have studied the influence of fever on syphilis by exposing infected rabbits to 42–43°C. for varying periods of time and state that a favorable influence was exerted upon the disease. Some have sought an explanation on the basis of meningeal hyperemia and other changes produced by malaria which results in an increased permeability of the tissues for spirocheticides like arsphenamin or neoarsphenamin generally administered after ten or twelve paroxysms; as previously stated histological studies of the brains of paretics treated during life by malarial inoculations, have shown

changes indicating improvement and of special significance, a marked reduction in the numbers of spirochetes in the tissues. The whole subject has been placed by most investigators into the category of non-specific protein therapy, but I believe this only confuses the problem and adds nothing to its solution.

As previously stated, it has been for years a matter of clinical experience that a disease may undergo retrogression when a second infection is superimposed. For example, in 1916, Zupnik, Miller, and Leiner[179] showed that malarial paroxysms in typhoid fever frequently bring about rapid clinical improvement of the latter, and the effect of erysipelas on sarcomata and of pregnancy on tumors are related phenomena. In other words the superimposed or secondary infection appears to stimulate immunological resistance of the tissues to the first infection; in this instance the malaria or relapsing fever parasites appear to greatly stimulate the resistance of the cerebral tissues to *Sp. pallida* which may result in producing a prolonged period of latency of the spirochetes and probably even the destruction of many of them. For this phenomenon the term "*stimulating immunity*" may be employed and this is quite similar to the "*depression immunity*" of Morgenroth, Biberstein and Schmitzer[180] who, in 1920, observed that mice infected with streptococci, develop in four to twenty-four hours a temporary and relative resistance to a second infection of the same or other streptococci in doses that prove fatal for control animals. In other words, the first infection appears to depress the reaction of the tissues to the second, but I prefer to think of the first infection as stimulating the resistance of the tissues as a whole to added infections of the same or other parasite and regard the influence of malaria and relapsing fever upon paresis as an example of *non-specific stimulating immunity*, the superimposed infection stimulating resistance to *Sp. pallida* in a non-specific manner.

Author's Method for the Specific Treatment of Early Asymptomatic Neurosyphilis.—Under this heading I refer to those cases of "spinal fluid syphilis" showing spinal fluid abnormalities without clinical signs or symptoms during the first six months to year or so after contracting the disease. In practice they constitute the approximate 20 to 25 per cent. of cases showing such spinal fluid changes as a slight increase of cells and protein, a weakly positive Wassermann reaction and possibly a colloidal gold curve of the luetic zone type, when examined after the first year of treatment following the chancre.

The treatment of this type of case is that of primary and secondary syphilis described in Chapter LXXII. As a general rule, intraspinal therapy is not required, although Gennerich[181] states that combined intravenous and intraspinal therapy is indicated and advises two intraspinal treatments after the spinal fluid has returned to normal followed by spinal fluid examinations every two or three months during the first six months after cessation of specific medication with subsequent examinations every six months for two or more years thereafter to detect possible relapses. When spinal fluid abnormalities are observed it is not advisable to ignore them or to trust to mercury by ingestion for their removal. More vigorous treatment should be continued and I am now employing sulpharsphenamin by intramuscular injection combined with mercury by inunction, giving a course of six weekly injections of the former in dose of 0.4 to 0.6 gm. with three inunctions of mercurial ointment per week (making 18 in the series). After two months rest this course is repeated or, if the sulpharsphenamin is objected to, eight weekly intravenous injections of neoarsphenamin are given with three weekly inunctions. If the inunctions are objected to, I give two weekly intramuscular injections of bismuth tartrobismuthate in dose of 0.2 gm., the course, under these circumstances, consisting of 8 injections of neoarsphenamin and 16 injections of bismuth, the latter totalling 3.2 gms. After another period of rest of several months, during which mercury by ingestion may be given, the spinal fluid is again examined. If still showing abnormalities, I believe that it is well to consider a series of four to six Swift-Ellis treatments consisting of an injection of either 0.6 gm. arsphenamin or 0.9 gm. neoarsphenamin every two weeks followed by the withdrawal of blood one half hour later and the intraspinal injection of serum next day as described on page 872. Tryparsamid should not be used, because experience has

shown that it is not especially indicated in this kind of case and there is risk of optic involvement.

Author's Method for the Specific Treatment of Late Asymptomatic Neurosyphilis.—This type of case refers to those discovered by spinal fluid examinations two years or more after the chancre stage. As a general rule, the interval is five to ten years or longer. There are no discoverable clinical signs or symptoms and sometimes not the slightest signs of fixation of the pupils. The spinal fluid shows an increase of cells and protein, a positive Wassermann reaction and a luetic zone colloidal gold curve; or the Wassermann reaction may be strongly positive with a paretic zone colloidal gold curve constituting what Moore and others have designated as "asymptomatic paresis" and corresponding to Southard's "paresis sine paresi." Not infrequently, however, the latter show some slight signs of neural involvement although there are no mental symptoms.

The treatment of such cases, and especially the latter, should be sufficiently vigorous and particularly since many are simply in the preparetic or pretabetic stages of neurosyphilis:

1. It is well to commence treatment mildly in order to avoid Herxheimer reactions, if more than a year has elapsed since the last course of treatment. The usual preparatory treatment is given in the way of correction of focal infections, advice regarding general hygiene and particularly of the mouth, etc.; alcohol should be forbidden or used in great moderation. For the first month specific medication may be of daily inunctions of mercury along with iodids by ingestion or weekly epifascial injections of 1 grain of succininmid of mercury or weekly intramuscular injections of bismuth tartrobismuthate in dose of 0.2 gm.

2. This is followed immediately by two months of arsenical treatment of which a choice may be made of the following: Weekly intramuscular injections of sulpharsphenamin in dose of 0.4 gm.; or weekly intravenous injections of tryparsamid in dose of 2.0 gm.; or weekly intravenous injections of neoarsphenamin in dose of 0.6 to 0.9 gm.; or weekly intravenous injections of arsphenamin in dose of 0.4 gm. I have named them in the order of my own preference. At the same time, it is well to administer mercury either in the form of weekly epifascial injections of the succinimid in dose of 1 grain or three weekly inunctions of mercurial ointment.

3. This is followed by a rest of one or two months when the course is repeated.

4. After another one or two months of rest, during which mercury by ingestion may be given, an examination of the spinal fluid is made along with a blood Wassermann reaction. If the reactions are negative, subsequent treatment may be milder in the form of courses of mercurial inunctions combined with iodid by ingestion and finally tapering off with mercury by ingestion.

5. If, however, the serological reactions are still positive it is well to continue with more vigorous combination therapy of mercury by inunction or intramuscular injection with intravenous injections of 3 gm. of tryparsamid every two weeks or weekly intramuscular injections of sulpharsphenamin, giving 6 to 8 injections of either or 3 to 4 alternating injections of each, as a course.

6. After a period of two to three months rest, during which, however, mercury by ingestion may be given, the blood and spinal fluid tests should be repeated. If negative reactions occur, the balance of treatment may be of mercury and iodids, gradually tapering off. If positive reactions are observed, however, more vigorous treatment is required in the form of com-

bined intravenous and intraspinal treatments by the Swift-Ellis or my own method at the rate of one every two weeks for a series of at least three.

7. Some of these cases are "Wassermann-fast" and demand periodical courses of treatment for several years as described in Chapter LXXV. Each case must be judged by its own special indications and the treatment advised is only in the nature of suggestions subject to modification. Even if negative blood and spinal fluid reactions are observed, it is well for the patient to continue under observation for several years with periodical mild courses of treatment to the extent at least of two months' courses of mercury and iodid by ingestion followed by periods of rest, after Fournier's chronic intermittent treatment (see page 1050).

Author's Method for the Specific Treatment of Meningovascular Neurosyphilis (Cerebrospinal Syphilis).—Under this heading I include cases sometimes possible of diagnosis on the basis of headache, dizziness and other signs present in paresis but without mental changes and presenting spinal fluid changes of high cell counts (due to meningitis), moderate protein, moderately positive Wassermann reactions and colloidal gold curves of the luetic rather than the paretic zone type. Many borderline cases occur however, in which the paretic gold curve occurs and sharp differentiation from incipient paresis cannot be made. As a general rule, there are also clinical evidences of myocarditis and aortitis.

In this type of case I believe that sulpharsphenamin and tryparsamid are to be preferred to arsphenamin and neoarsphenamin because less likely to produce vascular injuries; also bismuth is to be preferred to mercury or at least should be given interchangeably with mercury and the iodids are not to be omitted. Bismuth is especially indicated.

1. After the usual preparatory and hygienic treatment, specific medication should begin mildly in order to avoid Herxheimer reactions. My practice is to give weekly intramuscular injections of potassium tartrobismuthate in dose of 0.2 gm. for eight injections along with daily doses of iodids by ingestion.

2. This is followed by a course of eight weekly epifascial injections of sulpharsphenamin in dose of 0.4 gm. or weekly intravenous injections of tryparsamid in dose of 2.0 gms. If these are not given, neoarsphenamin may be injected intravenously in dose of 0.6 to 0.9 gm. once a week for ten weeks.

3. This is followed immediately by a course of daily inunctions of mercuro with iodid by ingestion for six weeks, the urine being examined weekly.

4. After a rest of two months the blood and spinal fluid are examined. If negative reactions are observed it is well to give an additional course of injections of sulpharsphenamin or neoarsphenamin or at least continue specific treatment with courses of mercury by inunction or injection or bismuth by injection, finally tapering off with mercury and iodids by ingestion.

5. If positive spinal fluid reactions are observed, even though the blood Wassermann reactions are negative, more energetic treatment is required and especially a combination of systemic and intraspinal therapy by the Swift-Ellis or some similar method. Patients presenting strongly positive spinal fluid Wassermann reactions with paretic curve colloidal gold reactions, are especially in need of vigorous treatment and careful clinical observation. My practice is to give a series of four or more Swift-Ellis treatments, substituting 0.9 gm. neoarsphenamin for 0.6 gm. arsphenamin, at intervals of two weeks. These are followed by a course of mercury by inunction and further treatment as indicated.

Author's Method for the Specific Treatment of Vascular Neurosyphilis.—Under this heading I refer to hemiplegia and thromboses due to syphilitic

infection of the blood vessels of the central nervous system. Practically all of these cases likewise show clinical or roentgenologic evidences of myocarditis and aortitis.

Treatment is indicated for the purpose of preventing, if possible, further vascular injuries and accidents as stated by Milian,[182] Nicand[183] and others, since great improvement may result. But great care is required in the selection and administration of remedies. As far as possible, intravenous injections should be avoided and particularly if any undue excitement attends the injections. Intramuscular injections of sulpharsphenamin, with mercury by inunction or injection, and large doses of iodids by ingestion, constitute the medicaments of choice. If sulpharsphenamin cannot be given, one may try small doses of neoarsphenamin (0.1 to 0.3 gm.) by intravenous injection, as described in Chapter LXXV for the treatment of chronic cardiovascular syphilis. Arsphenamin should not be used; tryparsamid is not especially indicated. In grave cases of cardiovascular syphilis when intravenous injections may be contraindicated the specific treatment of neurosyphilis may be conducted by the Ogilvie method of intraspinal medication, but in hemiplegia it is imperative to conduct spinal punctures and subarachanoid injections with more than usual care and, I believe, this should not be resorted to at all except under well controlled conditions providing for measurement of spinal fluid pressure and the prevention of undue excitement, increase of blood pressure and too sudden reduction of spinal fluid pressure.

Author's Method for the Specific Treatment of Tabes Dorsalis.—Many different methods or plans have been proposed for the treatment of tabes dorsalis. In early cases specific medication usually yields particularly gratifying results in the relief of pain and other symptoms but in all cases the chief purpose is to stop further progression of the disease with the realization that any nerve structures already destroyed cannot be restored, although the relief of pressure from edema and exudates upon nerve cells may result in a partial restoration of function.

1. It is particularly advisable to initate treatment by a thorough overhauling of the patient with special reference to the correction of focal infection, dietetic errors, constipation, alcoholic and other excesses, etc. Massage and educational muscular exercises may be indicated and especially in well-developed cases.

2. The first month of specific medication may be a thorough course of mercury by inunction with iodids by ingestion according to the Aachen or Hot Springs methods, as described in Chapter LXIII. It is imperative not to produce an exacerbation of the syphilitic processes (Herxheimer reactions) which may increase bladder, rectal and other disturbances and prove very difficult to check or control.

3. This is followed by a series of alternate intravenous injections of tryparsamid, in dose of 2 to 3 gm., and epifascial injections of sulpharsphenamin in dose of 0.4 gm., giving one injection per week for a course of twelve weeks (6 injections of each). If tryparsamid is not given, 8 to 10 injections of sulpharsphenamin may be administered; or 12 weekly intravenous injections of neoarsphenamin beginning with 0.45 gm. and increasing, or 6 weekly intravenous injections of arsphenamin beginning with 0.2 gm.

4. Immediately after this course or after a rest of one month, mercury and iodids should be given again for six to eight weeks, the former by inunction if possible. If inunctions cannot be given, potassium tartrobismuthate in dose of 0.2 gm. or the succinimid of mercury in dose of 1 grain may be injected intramuscularly once a week for eight to ten weeks.

5. After a rest of two or three months a blood Wassermann test and spinal fluid examination should be made. If satisfactory progress has not be obtained, intraspinal medication should be considered by the Swift-Ellis, Olgivie or some similar method. My preference is for the straight Swift-Ellis method every two or three weeks for a series of four or more, because this method produces the least cord and meningeal irritation and it is imperative to reduce these reactions to a minimum. The relief afforded by Swift-Ellis treatments is frequently so striking, and especially in early cases, that it is unwise to delay too long employing them in treatment. I believe they should be used whenever fairly energetic systemic treatment as outlined above, proves insufficient for checking the disease.

6. Subsequent treatment is guided by individual circumstances. As long as the blood and spinal fluid reactions are unchanged, specific medication should be continued, the kind and degree depending upon the tolerance and general condition of the patient. Among the arsenicals it would appear that preference is to be given to sulpharsphenamin, tryparsamid and arsphenamin in the order mentioned. Mercury by inunction and large doses of iodid by ingestion should be included. I am especially impressed with the value of combination therapy in these cases, giving as a course for eight weeks, 3 inunctions of mercury and 1 epifascial injection of sulpharsphenamin or 1 intravenous injection of tryparsamid per week along with daily doses of 40 to 60 grains of potassium or sodium iodid by ingestion. The number of courses given depends upon circumstances; at least two or three months of rest without treatment or with mercury by ingestion should be allowed.

7. In cases developing negative blood Wassermann and spinal fluid reactions, the degree of specific medication may be reduced, because a clearing up of the serology is almost always a safe indication of cessation of progress of the disease. In such instances I usually prescribe a course of eight weeks of mercurial inunctions with iodid by ingestion about three times a year for the following two years and then once or twice a year thereafter. If inunctions cannot be given, weekly intramuscular injections of either the succinimid of mercury or potassium tartrobismuthate are substituted. During the rest periods protiodide of mercury is generally given for a month or two at a time.

8. Sometimes in the course of specific treatment I administer an occasional intramuscular injection of one of the commercial milk preparations for the benefits accruing from non-specific protein reactions, especially in advanced cases, obviously under weight and of poor nutrition.

Author's Method for the Specific Treatment of Paresis and Taboparesis. In the management of active progressive cases of paresis and taboparesis, energetic specific medication is required and the results recently observed in cases treated with tryparsamid offers somewhat more hope for success than formerly. But even if tryparsamid is not employed, it should not be forgotten that energetic systemic treatment with arsphenamin and sulpharsphenamin combined with subarachanoid medication offers a good deal and especially in the treatment of early cases.

1. As in the treatment of all forms of chronic syphilis, it is required to pay particular attention to the removal of foci of infection and the correction of hygienic errors. Alcohol should be forbidden, as emphasized by Kelly,[184] who states that it may add to the gliosis of the brain in paresis. Physical and mental strain should be reduced to a minimum, although massage and exercise should not be overlooked. Constipation should be corrected.

2. Specific treatment may be initiated by giving six weeks of daily inunctions of mercury along with weekly intramuscular injections of potassium tartro-bismuthate in dose of 0.2 gm. and 40 to 60 grains of potassium

iodid daily by ingestion. If, however, the disease is rapidly progressing this initiatory treatment may be shortened with the prompt institution of arsenical treatment.

3. It would appear advisable to give 1.5 grams of tryparsamid intravenously once every week or 2 grams every two weeks for eight to ten injections. Otherwise one may give 0.4 to 0.6 gm. of arsphenamin or 0.9 gm. of neoarsphenamin intravenously or 0.4 gm. of sulpharsphenamin epifascially, once a week for six to ten weeks. A good plan is to give tryparsamid alternately with sulpharsphenamin. At the same time mercurial inunctions are given three or four times a week with 40 to 60 grains of iodid daily by ingestion or if the inunctions cannot be given, the succinimid of mercury may be injected intramuscularly once a week in dose of 1 to 1½ grains.

4. This is followed immediately or after a rest of one or two months if the disease has been checked, by a course of combined intravenous and subarachanoid treatments. My practice has been to use the Swift-Ellis method with reinforcement of the serum with 0.0005 gm. of arsphenamin or 0.001 gm. of neoarsphenamin. These are given every two or three weeks, the number depending upon the tolerance and reactions of individual cases. I have not used intraventricular and intracisternal injections, but believe that these routes, and especially the former, are deserving of more attention than they have hitherto received and particularly in the institutional treatment of severe progressing cases. During this period it may be advisable to give alternate intramuscular injections of either the salicylate of mercury or potassium tartrobismuthate in addition to the arsenicals.

5. It would appear that non-specific protein therapy may be worth while during the course of specific treatments, in the form of an occasional intramuscular injection of 0.5 gm. of sodium nucleinate or 5 c.c. of sterile milk or one of the commercial milk preparations. If tryparsamid is employed these may not be required, if the nutritional effects of this drug are produced.

6. The purpose of treatment is to produce clinical remissions. Even if serological remissions occur, treatment should not be interrupted unless there is a corresponding degree of clinical improvement. As long as energetic treatment is indicated, the courses described in paragraphs 3 and 4 may be repeated with suitable rest periods.

7. But it is not advisable to stop treatment during remissions, even in those remissions designated as "recoveries." This state is almost too good to be truly lasting and should be maintained by courses of mercury by inunction or intramuscular injection or occasional short courses of tryparsamid or sulpharsphenamin. Mental stress and hard work should be forbidden. Even under the best of circumstances it would appear that most cases in remission are a little "off" or "queer" and it is a mistake to entrust them with responsibilities until one is sure of their capabilities.

8. Malarial or relapsing fever therapy may be used and especially the former, but if the results reported with tryparsamid are substantiated by further experience, I see no particular use of resorting to malarial therapy in ordinary private practice, since the results produced by tryparsamid and sulpharsphenamin with or without subarachanoid medication, appear to equal or even exceed those reported from Europe with malarial therapy.

Prognosis in Neurosyphilis in Relation to Specific Treatment.—The prognosis of syphilis in general in relation of specific therapy is discussed in Chapter LXXIX but it may not be amiss at this place to briefly refer to the subject in relation to the treatment of neurosyphilis.

All writers on the subject have emphasized the importance of early and thorough treatment of syphilis as the best means for preventing neurosyphilis

and likewise as the best means for curing infection of these tissues. Neurosyphilis may be checked, but is seldom cured by haphazard and incomplete treatment; in such, relapses are frequent and usually due to residual infections. As so well stated by Collins,[185] the earlier treatment is instituted, the greater is the victim's chances of complete functional recovery and without those "scars of his mind and his emotions which permanently cripple him to some degree." For this reason the necessity for the early diagnosis and thorough treatment of neurosyphilis imposes a heavy responsibility upon all physicians undertaking the treatment of syphilis.

Neurosyphilis demands thorough treatment for a favorable prognosis; Harrison[186] states that he does not undertake its treatment at all and especially tabes, unless the patient is willing to persevere until he has received a substantial amount of the organic arsenicals; in his opinion it is better to withhold these unless thorough treatment can be given.

Best results are secured in the meningeal and vascular types including early cases of tabes, before ascending degeneration of the posterior columns of the spinal cord takes place. Advanced degenerations are of course irremediable; as stated by Harrison, "we may put out the fire but we can do nothing toward rebuilding the house and nature can do little." But pains and crises in tabes due to associated neuritis can be relieved. Furthermore, as stated by Fordyce, tabes progresses because the cause persists and as fresh segments of the cord are involved; this can be prevented in many cases by appropriate specific medication. It is true that spontaneous arrest of tabes and even of paresis may occur under ordinary treatment or with no treatment at all, as a result of the natural defensive agencies of the body, but, as stated by Fordyce, these should only encourage us the more in therapeutic endeavors. Solomon[187] believes that the majority of cases of syphilis of the nervous system, whether the so-called cerebrospinal syphilis, tabes dorsalis, general paralysis or other forms, are entitled to treatment, and if this is done thoroughly, intensively and systematically the results will be gratifying.

Thompson,[188] in a recent review of 53 cases of neurosyphilis treated by vaious methods concludes that intraspinal therapy is of value in neurosyphilis, that it should be given in connection with arsphenamin and mercury and that it is advisable at periodic intervals as long as the patient remains clinically or serologically positive.

CHAPTER LXXVII

SPECIFIC TREATMENT OF CONJUGAL AND CONGENITAL SYPHILIS

Some of the most difficult and perplexing questions in relation to the specific treatment of syphilis arise in connection with the subject of marriage and parenthood. These do not refer to those cases of syphilis in either sex contracted and thoroughly treated before marriage, but rather to those in whom evidences of syphilis are discovered after marriage and especially after children have been born. Can the father have syphilis without infecting either mother or child? Can the mother have syphilis without infecting the father or the child? These are matters that concern the question of specific treatment of the marital partners in such unions and it is in this sense that I am employing the term "conjugal syphilis" We are fairly certain of what should constitute the criteria of cure before marriage and parenthood may be safely sanctioned, but numerous cases arise in which a father is found to present evidences of syphilis after marriage of several years which immediately raises the question: Are the mother and children infected and thereby in need of specific medication, even though they do not show any definite clinical

or serological evidences of the disease? What is the proper procedure when a mother is found syphilitic under similar circumstances? Should the husband be treated? Should the children? Are we in position at present to lay down broad and uniform rules for the management of such cases? What are the criteria by which decisions may be reached, and no one experienced in the treatment of syphilis will deny the tremendous practical importance of these questions, involving as they may, the domestic peace and happiness as well as the health and even the lives of innocent and unsuspecting individuals. It is not so much a question of *how* such cases should be managed from the standpoint of specific therapy, because this is along the lines of the treatment of syphilis in general, but rather the question of diagnosis and the criteria by which decisions are reached regarding whether or not the spouse and children require antisyphilitic medication.

Great advances have been made in our exact knowledge of conjugal and congenital syphilis during the past twenty years by means of the Wassermann test and especially during the past ten years by careful and extensive clinical, sociological and serological studies employing improved methods, but there are still many and wide gaps in our information on these subjects. Percentages expressing the incidence of infection under this or that condition aid us in arriving at decisions, but in many cases it is after all a matter of expressing opinions with a full realization that only the future welfare of the individuals concerned can tell us if we are right or wrong.

In this chapter I shall endeavor to present my opinions of the subjects concerned and the reasons upon which they are based, along with methods for the specific treatment of various types of congenital syphilis; the subject of conjugal syphilis will be discussed only from the standpoint of whether or not specific medication is indicated, because if this is decided upon, the methods advised have been already presented in preceding chapters.

Terminology.—But before entering upon a discussion of these subjects it may be well to define the meaning of the terms conjugal and congenital syphilis as employed in this chapter. *Conjugal syphilis* refers to the infection of the spouse (man or woman) by reason of the marital relation and will be discussed from the standpoints of diagnosis and specific therapy. *Congenital syphilis* refers to the infection of a fetus in the uterus with *Sp. pallida*. It does not include, therefore, those exceptional cases of syphilis of children contracted during birth or shortly thereafter by contact with chancres, mucous patches or other open lesions of the mother or wet nurse; these constitute examples of *infantile syphilis*. The term *prenatal syphilis* may be used as a synonym for congenital syphilis, but the terms *hereditary syphilis* and *heredo-syphilis*, so frequently employed by French writers, are misnomers, because an actual parasite and disease are transmitted rather than a physical or mental trait or characteristic of the parents. *Conceptional syphilis* is applied to those cases of congenital syphilis in which it is believed that *Sp. pallida* infects the ovum at the time of conception: by paternal transmission, if the parasite is contained in the semen, or by maternal transmission, if the parasite is from the blood or tissues of the woman.

Syphilis and Marriage in Relation to Specific Therapy.—Owing to the frequency with which syphilis is transmitted to the spouse and offspring, the subject of syphilis and marriage has very properly attracted a great deal of attention and especially in relation to public health. Many statistical studies have been published which need not here be reviewed, as our present interests concern the matter of how much specific treatment should be given either the man or woman before marriage may be sanctioned, in order to be fairly sure that the spouse and offspring will not be infected. In a way, the subject resolves itself into a discussion of the criteria of cure because the only safe time to marry is when there are good reasons for believing that the individual has been cured. Furthermore, our standards and criteria are more strict than laid down by Fournier and other older syphilologists, because they had only clinical signs for their guidance, whereas we have the Wasser-

mann test in addition, which has added very materially to our knowledge of conjugal and congenital syphilis during the past fifteen years.

Since physicians are very frequently asked questions bearing upon marriages involving syphilitic individuals, I am stating here the rules by which my opinions are guided, these being in conformity with the practice of many leading and experienced syphilologists:

1. Patients seen and placed upon intensive treatment during the chancre stage and before the Wassermann reaction has become positive may be allowed to marry after at least one year of vigorous treatment followed by a second year of observation and milder treatment as described in Chapter LXXII, provided there have been at no time secondary manifestations or serological evidences of infection in the blood and spinal fluid.

2. Patients seen and placed upon intensive treatment during the late primary stage or in the secondary stage after the Wassermann reaction has become positive may be allowed to marry after two years of vigorous treatment followed by a third year of milder treatment and observation, during which there have been no clinical manifestations of the disease, repeatedly negative blood Wassermann reactions and at least one complete examination of the spinal fluid with negative results.

3. Patients seen in the latent and tertiary stages of syphilis with positive Wassermann reactions, may be allowed to marry after thorough courses of treatment over a period of at least two years followed by a third year of milder treatment and observation as described in Chapter LXXV, during which there should be absolutely no clinical evidences of syphilis, repeatedly negative blood Wassermann reactions and at least one complete examination of the spinal fluid with negative results. A provocative Wassermann test is advisable as described on page 519.

4. A *man* with a persistently positive blood Wassermann reaction may be allowed to marry if there has been at least three years of vigorous treatment and if the spinal fluid shows no abnormalities; in the majority of such instances both the spouse and children escape infection, *but it cannot be stated that the union is absolutely free of the danger of transmission of infection* and many physicians, including myself, naturally hestitate to sanction marriage under these conditions. A *woman* under these conditions, however, should not marry at all because she incurs a much greater risk of transmitting the disease to offspring; there is likewise a slight risk of transmission to the spouse.

5. A *man* or a *woman* with a persistently positive blood Wassermann reaction and the spinal fluid changes of neurosyphilis should not marry, regardless of the amount of specific treatment received, because under these conditions, there is more risk of transmission to both spouse and children.

The above mentioned conditions are definite and probably most physicians will agree in whole or most part with the conditions laid down in relation to marriage, but there is a larger group of more puzzling cases in which an opinion must be very guarded because of the impossibility in some cases of detecting latent syphilis by the most thorough physical, serological and roentgenological examinations. Such cases are somewhat as follows:

6. If the patient is certain of having contracted syphilis several years previously, followed by a period of specific treatment, I believe that marriage may be sanctioned if a thorough physical examination reveals no evidences of the disease and the blood and spinal fluid reactions are negative. I refuse an opinion unless a spinal fluid examination is permitted and, I believe, that a provocative Wassermann test is advisable. If the latter is conducted, the spinal fluid examination should be made when the provocative blood tests are conducted, in order to obtain the value of provocative spinal fluid reactions, if such occur. If in spite of negative and favorable results of these kinds the patient and the physician wish to be on surer ground, a year or two of treatment may be given during which repeated physical and serological examinations may be made. In this case the year of specific treatment replaces the provocative injections of arsphenamin or neoarsphenamin and it may be fashioned along the lines described in Chapter LXXV for the treatment of asymptomatic late syphilis.

7. If the patient, an old syphilitic, is unable to give a definite and clear account of his infection and of his previous treatment, greater caution is required. Likewise in cases of either sex with indefinite but suggestive venereal histories, a woman with a history of miscarriages, etc., a thorough physical examination should be made along with blood Wassermann and complete spinal fluid examinations. A provocative Wassermann test is advisable and I always advise one probationery year during which at least two physical and four blood Wassermann tests are made; it is not usually necessary or advisable however, to repeat the spinal fluid examinations. If these examinations fail to disclose evidences of the disease, marriage may be sanctioned but it is necessary to employ a sensitive complement-fixation test because of the danger of falsely negative reactions in the presence of extremely latent syphilis.

Conjugal Syphilis in Relation to Antisyphilitic Treatment of the Spouse.—Under this heading I wish to discuss with a little more detail the question of transmission of syphilis to the partner of a sexual union in relation to the matter of specific treatment, before taking up the subject in relation to the offspring. Whenever syphilis is discovered in a husband or wife, the question of the management of the spouse arises and frequently presents difficult problems and situations.

It scarcely requires stating that a syphilitic of either sex, with open lesions and especially chancres and mucous patches, runs grave risks of infecting the sexual partner and especially by repeated contacts. In addition there are risks of extra genital infection and marriage at least, can never be sanctioned under such circumstances.

But in the presence of clinically latent syphilis without demonstrable open lesions, what are the chances of infection of the spouse? The subject must be discussed separately according to the sex of the syphilitic partner.

A syphilitic husband under these conditions is far more likely to infect his wife than is a syphilitic wife likely to infect her husband. She runs the risk of infection by three ways, namely, contact with an open lesion of the husband which may develop at any time; contact with his semen carrying *Sp. pallida*, and thirdly, the possibility of infection from a syphilized fetus, if it is granted that paternal conceptional syphilis may occur. The husband, however, is liable to infection from a syphilitic wife only in case he comes in contact with open lesions, if such develop in the course of years.

Infection of a wife by contact with the open lesions of a husband requires no discussion; if one can be certain that the disease has been latent through the period of marital relationship, infection of the wife by this route may be excluded. But I believe she may be infected by the semen direct without involving the question of pregnancy and especially if her husband's testicles are infected with *Sp. pallida*, as is now regarded of frequent occurrence even in the absence of clinical signs of infection. In such cases the disease may run a very mild course without its presence being suspected, the wife being entirely ignorant of infection (*syphilis ignota*), because the spirochetes are of greatly reduced virulence.

But is it possible for a woman to carry a syphilitic fetus and yet escape the disease? Some physicians believe that *Sp. pallida* or rather a smaller spore-like form of the parasite may infect the ovum direct (*paternal conceptional syphilis);* but may the mother escape through the destruction of spirochetes by placental ferments as stated by Routh[1] or some other means? Jeans[2] has found that 85 per cent. of mothers of syphilitic infants gave positive Wassermann reactions. But what is the status of those who do not and who present no clinical evidences of the disease? For my own part I believe that we should regard all mothers of syphilitic children born at or near term, as syphilitic and place them on antisyphilitic treatment. It may be that a woman aborting a syphilitic fetus, before the third month, may escape infection but I doubt this and feel absolutely sure that all women with a history of two or more syphilitic pregnancies should be placed on antisyphilitic treatment. Indeed, an increasing number of syphilologists believe that paternal infection of the ovum does not occur and that a syphilitic fetus always indicates that the mother is syphilitic and that she was infected before conception occurred. In other words, according to this view, a syphilitic fetus always indicates syphilitic infection of the mother and I subscribe to this opinion at least to the extent of always advising antisyphilitic treatment of the mother even though her blood Wassermann test may yield a negative reaction.

Indeed, I know of no other type of syphilis more likely to yield *falsely negative* Wassermann reactions unless it be latent congenital syphilis of children.

However, it must be granted that a woman married to a man infected with syphilis five or more years previously, may escape seminal and fetal infection if her husband's disease has been latent. But our opinion in each individual case must be based only upon thorough physical and serological examinations because if the wife is syphilitic, the disease is apt to be very latent and defy detection even by thorough and sensitive tests. However, we must have some criteria for judging whether or not the wife of a syphilitic man requires antisyphilitic treatment and I believe that treatment may be *omitted* under the following conditions: (*a*) When there are no manifest or suspicious clinical evidences of syphilis; (*b*) when repeated Wassermann tests by a sensitive and acceptable method yield negative reactions; (*c*) when there is no history of spontaneous abortions or miscarriages; (*d*) when the child or children show no clinical or serological evidences of syphilis. To these may be added negative provocative blood Wassermann and spinal fluid reactions, although these cannot usually be applied when conditions demand or warrant the secret investigations of spouse and offspring.

But if these are acceptable as criteria for the omission of specific medication for the wife of a syphilitic man, what are the indications for the institution of treatment? I believe these may be stated as follows: (*a*) The presence of even suspicious clinical manifestations even though Wassermann reactions are negative; (*b*) the occurrence of a positive Wassermann reaction, even though there are no clinical manifestations; (*c*) the birth of a syphilitic fetus or child even though there are neither clinical manifestations nor positive Wassermann reactions in the mother. If the blood Wassermann reactions are negative but the spinal fluid shows abnormalities, treatment should be instituted.

As a general rule, most reliance is placed upon the results of Wassermann tests and especially since these are frequently the best examinations possible when conditions demand an investigation without disclosing its purpose. As repeatedly stated it is imperative that these tests shall be done with a method as sensitive as consistent with specificity because even under these circumstances we are always apt to secure falsely negative reactions. After a woman has lived with a syphilitic man for several years we can never be absolutely sure of her having escaped infection; for example, as shown by Veeder[3] at least 86 per cent. of mothers of syphilitic children yield positive Wassermann reactions indicating syphilitic infection even though there are no demonstrable clinical evidences and the women are ignorant of being infected (*syphilis ignota*). At best we may say that in the absence of all manifest or suspicious clinical and serological evidences of infection, that antisyphilitic treatment need not be given but that there should be subsequent and periodic clinical and serological examinations over a period of several years. As a general rule these may be managed even when it is necessary to proceed secretly in order to preserve domestic peace and happiness. But no physician should be a party to any agreement by which the spouse is neglected and left to her fate; with tact and good judgement the physician may readily do his duty even in difficult situations when suspicion has greatly sharpened the intellect of the spouse.

The reversal of these conditions may present just as puzzling a situation, that is, when syphilis is brought into a marital relationship by the woman. If she presents early open lesions it is almost sure that the husband will become infected with the production of a chancre and the usual clinical course of syphilis. But in the absence of these, what are the chances of

infection of the husband when the disease in the wife is chronic and latent with no demonstrable open lesions? The possibilities of his contracting the disease are very much less than when the conditions are reversed and the syphilitic partner is the male. But yet there is danger of infection and especially after marriage of several years. Evidently small open lesions may develop about the woman which do not attract attention and curiously enough, the man may not notice a chancre or other manifestations of sufficient degree to attract attention, the presence of the disease being unsuspected because he is ignorant of the possibilities of infection. Numerous instances are on record of neurosyphilis in the husband contracted from marriage with a neurosyphilitic woman although in most cases the reverse pertains. Evidently the spirochetes, derived from small undetected lesions about the woman, are of greatly reduced virulence and produce undetected lesions at the point of entry. Therefore, if syphilis has been introduced into a marriage by the wife, the husband should be examined for evidences of infection and when this must be secretly done, I know of no more difficult situation. As a general rule, it is possible to arrange for a physical examination and a blood Wassermann test at least and if the latter is positive by a sensitive and acceptable method, it may be assumed that the husband is infected and in need of specific treatment. If these examinations are negative a provocative Wassermann test and examination of the spinal fluid should be done if possible; if these are negative we may at least state that there are no indications for antisyphilitic treatment although we may not be absolutely sure that latent syphilitic infection is absent.

When syphilis is discovered in either spouse under such conditions, it is almost impossible to give thorough treatment without disclosing its purpose; at least, in my experience, it is difficult to secure proper cooperation until the patient understands the purpose of treatment. I have in many cases, however, given courses of neoarsphenamin by intravenous injection on the assumption that these were required for the correction of anemic states and have succeeded in administering mercury by inunction in the form of 85-per cent. calomel ointment under the disguise of massage. Mercury and iodid at least may be easily given by ingestion over long periods of time after Fournier's chronic intermittent method described on page 1050. But if possible the plan of therapeutic attack should be along the same lines as advised in Chapter LXXV for the treatment of chronic syphilis according to the condition of the spouse, although modifications are usually demanded by the individual conditions and circumstances of each patient.

Conjugal Syphilis in Relation to Antisyphilitic Treatment of Children.—Having thus considered the matter of antisyphilitic treatment of the spouse involved in a marriage with a syphilitic, we may now take up the subject of treatment of the children of such a union. Of course, if the child shows clinical or serological evidences of syphilis, treatment is to be given regardless of which marital partner is responsible for the disease. But not infrequently the matter of specific medication is difficult to decide when the offspring does not show clear-cut evidences of infection. Here again our decision is greatly influenced by whether it is the mother or father who is syphilitic.

Can a syphilitic father beget a non-syphilitic child? During the early acute stages of the disease the answer is "no" in almost all cases. But in the chronic latent stages it would appear that this is possible and indeed, of frequent occurrence *if the mother has escaped infection.* Under conditions of extreme latency, his semen may not be infectious and both the mother and child may escape infection, insofar, at least, as may be determined by thorough physical and serological examinations. But even though the syphilitic

father has apparently not infected the mother and even though the children are borne without the usual manifestations of syphilis great care and skill are required in the physical examination of the offspring for unusual evidences of syphilis. As pointed out by a commission of French syphilologists composed of Jueyrat, Hudelo, Spillmann, Gastrou and Simon,[4] it is a well-recognized fact that an old syphilitic without infecting his wife, may have offsprings with various dystrophies, although the children may not have active syphilis. It is suggested that these dystrophies may be due to a toxic action on the spermatozoa by the spirochetes in the father.

If the mother is syphilitic either because of infection before or after marriage, it is likely that the child or children are infected. Cooke and Jeans[5] found evidences of syphilis in at least 70 per cent. of the children of Wassermann-positive mothers. Evidences of placental syphilis were observed by Jeans and Cooke[6] in only 27 per cent. of cases, all of these children showing clinical evidences of syphilis, but it is now known that a child may be borne with syphilis without an examination of the placenta disclosing the presence of *Sp. pallida* or histological evidences of infection.

What should influence our decision on the question of antisyphilitic treatment of the offspring if the father is found syphilitic and the mother apparently free? This involves the question of whether it is possible for the father to infect the ovum direct and bring forth a syphilitic child without infection of the mother. Golay[7] and others believe this possible; Moore[8] and others are opposed to the theory. The question cannot be settled in a definite manner and while it may be granted that a small form of *Sp. pallida* may enter the ovum along with a spermatozoön, I cannot conceive how conception can be followed by the development of a fetus unless the parasites are of an extremely reduced virulence, which is highly improbable. In such cases I believe that treatment may be safely omitted if the offspring are in good general health and nutrition, free of dystrophies and if they yield a *series* of negative Wassermann reactions by a sensitive method over a period of several years. I do not believe that a decision can be made on the basis of a single examination; observation and repeated clinical and serological examinations are necessary for reaching a final decision. If, however, the child is subnormal mentally or physically, persistently undernourished and of lowered resistance to bacterial infections, persistently anemic, etc., I believe that we should aim to be on the safe side and advise antisyphilitic treatment even though the Wassermann tests yield negative reactions. Furthermore, it is advisable to examine the spinal fluid since the frequency of neural infections in children with spinal fluid changes has been shown by Findaly,[9] Lavergne,[10] Leitch,[11] Kingery,[12] Tezner,[13] Hunt,[14] Ong and Selinger,[15] Fordyce and Rosen[16] and others; the importance of these fluid examinations in congenital syphilis has not been appreciated as much as the results of these investigations indicate and especially when the blood tests yield negative reactions. Just as we would hesitate to express an opinion upon the absence of syphilis in an adult on the basis of negative blood Wassermann tests, so should we hesitate in cases of late congenital syphilis.

If the mother is syphilitic and the father apparently free of infection or if both mother and father are syphilitic, we should be extra cautious in expressing our opinion on the absence of syphilis because the offspring are so much more likely to be syphilitic. Indeed, I believe they should be regarded as syphilitic and treated accordingly until proven otherwise, although I admit that, according to our best methods of detecting syphilis at present, it is to be stated that a mother with latent syphilis may bring forth a non-syphilitic child. Sylvester[17] believes that every child of a syphilitic mother should

receive some treatment after birth irrespective of negative Wassermann reactions and the absence of symptoms; Almkvist,[18] Fordyce and Rosen,[19] however, believe this practice is an unnecessary hardship and that in the absence of clinical and serological evidences of infection in the offspring of Wassermann positive mothers, treatment may be omitted while the child is carefully observed over a period of years. Such children require extraordinary physical and roentgenological examinations for epiphysitis along with Wassermann tests by a most sensitive method and especially if they present no manifest clinical indications of infection. It should never be forgotten that a negative Wassermann reaction may be followed later by positive reactions and especially in latent infections; for this reason physicians should refuse to express a negative opinion on the results of a single examination or test. We may state that in the presence of negative findings, antisyphilitic treatment is not indicated but be careful to add that this cannot be accepted as an opinion that syphilis does not exist; in other words, such children should be kept under observation with occasional blood tests. On the other hand, a blood test of a child made during the first two weeks after birth may yield a positive reaction to be followed later by a negative reaction. What does this signify? Jeans and Cooke, Fordyce and Rosen and others believe that it may be possible for a child to be born free of syphilis but carrying in its blood for a few weeks the Wassermann antibody derived from a syphilitic mother. I do not have evidence to positively refute this assumption; nor do I deny the possibility of its occurrence, but I believe it is a risky assumption and that the phenomenon may be due to a development of latency of the infection; in short, I believe and practice in the institution of antisyphilitic treatment for infants falling into this category.

May a syphilitic mother beget a non-syphilitic child? If her infection is light and latent the question must be answered "yes" in those cases in which there are absolutely no clinical or serological evidences of syphilis over a period of years. Apparently in such instances the child has escaped because the lesions of the mother did not involve the organs and tissues of generation and because periods of spirochetemia did not occur during the period of pregnancy. But as stated above physicians should exercise great caution in the expression of an opinion on the absence of syphilis in a child where the mother is known to have the disease, unless she became infected after the eighth month of pregnancy, in which case, the child may be borne before infection occurs.

Types of Congenital Syphilis in Relation to Specific Treatment.—It is obvious that the kind and amount of specific medication required in congenital syphilis will vary according to the severity and extent of the disease. That the infection itself is subject to wide variations is well known, since it may range all the way from an infant overwhelmed with *Sp. pallida* at birth and succumbing within a few days, to one born without clinical manifestations and showing no evidences for several years and indeed, in not a few cases, until adolescent and adult ages are reached. The only explanation that may be offered for the wide clinical variations refers to the matter of virulence of the infecting organisms on one hand and immunological resistance of child and mother on the other. If the ovum is infected with *Sp. pallida* at the time of conception it is difficult to understand how it can survive and develop; for my part I cannot accept this at all unless the parasites are of greatly reduced virulence. At all events, if conceptional syphilis does occur it is reasonable to expect intrauterine death of the fetus in most cases with a wide distribution of the parasites in the fetus associated with faults in development of the organs, in the cases of survival.

Congenital syphilis due to acute early syphilis of the parents frequently ends in intrauterine death; if the fetus is born viable there are usually well marked clinical manifestations and a poor prognosis. Congenital syphilis due to late syphilis of the parents however, is generally a much milder infection and with a much better prognosis, because the spirochetes are of reduced virulence, on the one hand, with the possibility of a transmission of immunity principles from mother to child, on the other; however, there is so little evidence in support of the latter hypothesis, that most reliance must be placed upon the question of the virulence of *Sp. pallida* as determining the fate of the child. It is sometimes stated that the well known fact that a syphilitic mother may finally beget an apparently non-syphilitic child after preceding syphilitic children, is due to the acquisition of immunity in the mother transmitted to the child; undoubtedly immunity plays an important rôle, but in my opinion it acts by reducing the virulence of the spirochetes in the tissues of the mother, rather than by placental transmission of antibodies.

Clinically several types of congenital syphilis may be therefore encountered, largely determined according to the virulence or latency of the infection in the parents:

A. *Acute symptomatic congenital syphilis* presenting at birth various skin and mucous membrane lesions, snuffles, visceral involvements, poor physical condition and a positive Wassermann reaction. Many of these infants die in a few days and faulty development, poor musculature and reduced resistance greatly complicate specific therapy. Prompt intramuscular treatment however, frequently works wonders with a rapid transformation of the infant's condition. This type of case, however, fares badly on the older forms of treatment consisting of inunctions of mercury by the binder or gray powder by mouth.

B. *Acute asymptomatic congenital syphilis* in which the child is well-developed, well-nourished, presents no manifest lesions at birth but yields a persistently positive Wassermann reaction not only within the first two weeks after birth, but beyond this time. I call this type "acute" because the serological reactions indicate an activity of the spirochetes but in tissues not physiologically important and hidden from view, as in the epiphyses of the bones, liver, spleen, etc. This type does very well under vigorous treatment and generally gives a good prognosis.

C. *Late congenital syphilis.*—This group is a very large one and includes those children born apparently healthy and continuing so for several months to several years, when they loose weight, are poorly nourished, develop anemia and secondary infections, epiphyseitis with pseudo-paralyses, cutaneous, osseous or other visceral lesions. The Wassermann reaction is usually positive but may have been negative at birth and is subject to wide variations in the same case at different times according to the fluctuations in spirochetic activity. No other type of syphilis requires more diagnostic acumen and experience than these cases and, indeed, may require the cooperation of several specialists for diagnosis. Sometimes the clinical and serological manifestations are delayed for years and even to adult age. No part of the body is immune to infection and lesions may be found in the eye (especially interstitial keratitis) any time from one year to middle life. In one of my cases the disease was first detected in a physician twenty-six years of age. Neurosyphilis may be detected by spinal fluid examinations in some cases as early as one year of age but clinical manifestations are not usually apparent for five to ten years later.

The specific treatment of these cases is always a prolonged and tedious procedure requiring for success the complete and hearty cooperation of the parents or of the patient, when treatment is undertaken later in life. In many of them, probably the majority, and especially those ranging from five years to adult age, the infection is ground into the tissues as it were, and proves very rebellious, many belonging to the Wassermann-fast group of syphilitics. But many of the lesions disappear under persistent treatment unless they are due to faults in development. Interstitial keratitis, for example, is not as resistant as many text-books state, when adequate intravenous and intramuscular treatment is given. It is true that this and other late lesions are resistant to medication with mercury and iodids by mouth or inunction, but treatment with neoarsphenamin and sulpharsphenamin along with mercury by injection and iodids by ingestion, are doing a great deal more for these patients than has hitherto been the case. It is true, however, that the treatment of this group must be prolonged because the disease is chronic, just as prolonged treatment is required in chronic acquired syphilis. During the first five years the prognosis is greatly influenced by such conditions as digestion and gastro-intestinal disturbances interfering with nutrition, by intercurrent infections and general resistance, etc.; in older children and

adolescents, the prognosis is uniformly better. Among adults, however, there is danger of transmission to the second generation although, in my limited experience, I have encountered but two apparently genuine instances of undoubted second generation infections. Complete and convincing evidence of truly second generation cases is difficult to obtain, satisfactory proof requiring, in the opinion of Higoumenakis,[20] fulfilment of the following conditions: (*a*) The grandchild must present a lesion or dystrophy which is unmistakably syphilitic, and which is not acquired; (*b*) One of the parents must be affected by congenital, but not by acquired, syphilis and the other parent must not have acquired syphilis; (*c*) One of the two parents of the first congenitally affected progenitor—and therefore a grandparent of the affected subject of the second generation—must have acquired syphilis. This author has collected 9 cases reported since 1904 and has added 13 observed by him personally; Riviere[21] has also reported a case. Clinically the lesions and symptoms of second generation syphilis are the same as occur in first generation infections and the treatment is likewise similar.

With modern methods of treatment the prognosis in congenital syphilis is very much better than formerly. Indeed, as stated by Nobl and Remenobsky[22] the prospects of a child surviving infancy are very good and much better than under the older methods of diagnosis and treatment. Syphilitic children appear to withstand the effects of antisyphilitic drugs very well indeed; jaundice, dermatitis and other accidents of arsenical therapy are much less frequent than among adults. On the other hand, complete eradication of the disease is very difficult to the extent of producing a state of persistently negative Wassermann reactions by a sensitive method, even though external lesions may be dissipated. The spirochetes are usually thoroughly disseminated throughout the organs while only a single particular lesion like an interstitial keratitis may be apparent. The great and most important feature is the prevention of congenital syphilis by thorough treatment of potential parents and the treatment of syphilitic women during pregnancy. Of course, faults in development of syphilitic children cannot be corrected even though the disease is held in check or even eradicated. Likewise many of the late lesions are difficult to control or to correct; in other words, some of the injuries produced by *Sp. pallida* in congenital syphilis are no more amenable to correction than in acquired syphilis and especially injuries of the central nervous system. As stated by Morgan[23] the reduction of the mortality alone is not the whole problem in congenital syphilis; in 138 of his cases, 3 per cent. were deaf; 3 per cent. had permanent deformities of the palate, nose, etc.; 8 per cent. had permanent impairment of vision and 12.3 per cent. were mentally deficient. In other words, over 25 per cent. were handicapped in the struggle for existence with permanent physical defects and diminished earning capacity.

Incidence of Congenital Syphilis in Relation to Specific Therapy.—No one can state the incidence of congenital syphilis at the present time, but it is a safe prediction that, under our present methods of treatment, the incidence is decreasing. This is true because we are learning to treat acquired syphilis of men and women much more thoroughly than in former years which reduces the incidence of transmission; furthermore, we are learning the great value of treatment of syphilitic women during pregnancy as an effective means for preventing transmission. The widespread interest in this phase of the modern control of syphilis with the establishment of prenatal clinics, in which syphilis of prospective mothers may be detected and treatment promptly instituted, is alone a great step in advance. Churchhill and Austin[24] have calculated that from an analysis of the literature the incidence of congenital syphilis varies from 2 to 14 per cent. being from 2 to 6 per cent. in our large American cities and 3.3 per cent. in their own experience. Roberts[25] has recently estimated that 10 per cent. of all marriages involves a syphilitic; that 75 per cent. of all offsprings from marriages involving syphil-

itics have syphilis; that 25 per cent. of all fetal deaths are due to syphilis and that 78 per cent. of all syphilitic infants born alive succumb during the first year of life. Jeans[26] states that Wassermann surveys have shown that 9.5 per cent. of adults admitted to hospitals and dispensaries in five of our large American cities, showed positive reactions; that 9.6 per cent. of 5,358 pregnant women in five large cities yielded positive reactions; that the incidence of fetal deaths in syphilitic families have varied according to twelve investigators from different parts of the world, from 17 to 62 per cent. with an average of 30 per cent. while the apparent rate in non-syphilitic families is about 9.7 per cent.; that 30.2 per cent. of infants in syphilitic families die early in contrast with a mortality of 15 per cent. among children of apparently non-syphilitic parentage.

In view of the fact that Wassermann tests and clinical examinations are apt to fail in the detection of many cases of congenital syphilis it is entirely likely that these figures are conservative; at least, the known incidence is alone sufficient for arousing our keenest interest in the subject of the adequate prophylaxis and treatment of syphilis as a means for reducing this tremendous waste of life and health. It may be that the incidence during the next ten years will show little or no change, because, while the true incidence is being reduced by better methods of treatment, more efficient means in diagnosis are likely to be developed with the detection of cases escaping diagnosis at the present time. But I believe it is certain that our present day methods of treatment are reducing the incidence of congenital syphilis and especially by reason of the increasing tendency to investigate the matter of probable syphilis in pregnant women and the prompt institution of treatment when evidences are found; this subject of the prenatal treatment of syphilis may be now discussed with a little more detail.

Prevention of Congenital Syphilis and the Prenatal Treatment of Syphilis. The *prevention* of congenital syphilis refers to such measures as will prevent access of *Sp. pallida* to the child during pregnancy. From the standpoint of the father it means that the parasites must not be present at the time of conception and that he must not infect the mother during the subsequent period of pregnancy. If the *husband* is a syphilitic, a shorough course of treatment should be given in preparation for parenthood, which should be continued as long as sexual relations are held with his wife. If the *wife* is syphilitic, thorough treatment should precede conception and should be continued during pregnancy. If she becomes infected after conception, vigorous antisyphilitic treatment is indicated to prevent, if possible, the access of spirochetes to the fetus; if infection occurs after the eighth month the fetus may be born at term before spirochetemia of the mother and infection of the child occurs, but even though she is infected in the last few weeks of pregnancy, intensive treatment should not be omitted. These, therefore, are measures for the prevention of congenital syphilis.

Prenatal treatment of syphilis strictly refers to the treatment of the fetus through the mother, but may amount to the prevention of syphilis of the child if the treatment of the mother is given early enough to prevent infection. What should be done if the father is syphilitic but the mother presents no clinical or serological evidences of the disease? Is it safe to omit antisyphilitic treatment or should treatment be given? In past decades Fournier, Finger, Gaucher and others believed in the routine treatment of any pregnant wife of a syphilitic man in the interests of the unborn. Carle[27] states that, while he formerly adhered to this practice, he now no longer does so because secret treatment with mercury in pills and syrup is not usually intensive enough anyhow in case the woman is syphilitic and that he prefers to decline

treatment unless the woman shows some evidences of infection, in which case more intensive medication should be given. In my opinion a good deal depends upon the stage of the disease in the father. If more than five years have elapsed since his chancre, with fairly thorough treatment in the meantime, with no clinical evidences of syphilis although the Wassermann reaction is positive, treatment of the mother may be omitted; but if the father's infection is more recent, if his history is uncertain or cannot be ascertained, or, if it is decided to "take no chances" insofar as this is possible without promoting suspicion and discord, I believe it is well to administer antisyphilitic treatment to the mother even though it may be uncalled for and unnecessary in some cases. But what kind of treatment should be given? In the interests of domestic peace and happiness it is frequently advisable to give specific medication without arousing the suspicions of the wife. This of course presents many difficulties. If the father's infection is known to be old and latent it may suffice to give daily inunctions of calomel ointment for a month, followed by bichlorid of mercury and potassium iodid in a syrup by ingestion for a month, followed again by inunctions on alternate months throughout pregnancy. It is frequently possible to give this kind of treatment without exciting suspicion, the inunctions being administered under the disguise of massage.

But if the father's disease is more recent and active, the chances of prenatal infection are much greater and the mother should receive more intensive treatment, to be shortly described. Likewise, if the mother shows a positive Wassermann reaction, regardless of whether or not the father is syphilitic or the stage of his disease, specific treatment is indicated. Stokes[28] believes that practically all women known to have had syphilis should undergo some treatment during pregnancy with due regard for her kidneys, liver and eliminative mechanism in general since these are already under increased burden from the pregnant state. Givan[29] has reported that twenty children of syphilitic women energetically treated during pregnancy yielded negative Wassermann reactions while eleven out of a series of fifteen children of untreated syphilitic mothers, yielded positive reactions. Williams[30] has reported an exceptionally comprehensive study of 96 syphilitic women who had passed through 113 pregnancies, the children being observed for periods ranging from four to twenty-eight months after birth. A particularly valuable feature of his study was the fact that the women were under observation for years enabling him to determine the influence of syphilis on fetal mortality *before* and *after* treatment in the *same* patients. Williams concluded that almost ideal results follow anything like efficient treatment of syphilitic pregnant women and that surprisingly good results may sometimes follow what would ordinarily be regarded as altogether inefficient treatment in men or in nonpregnant women, which would seem to indicate that pregnant women are unusually amenable to antisyphilitic treatment. One woman, however, had received thirty injections of arsphenamin without changing the positive Wassermann reaction, but she gave birth to a child having no evidence of syphilis, and nine months later the child had a negative Wassermann reaction. Williams believes there is something about the pregnant woman which mitigates the virulence of the disease and predisposes to a spontaneous cure. He insists on the early recognition of maternal syphilis so that a healthy child may be born and the mother cured more easily.

Almkvist[31] has recently reported that of 28 untreated syphilitic mothers, 27 bore infants that had manifest signs of syphilis in from 15 days to 8 months after birth; of 39 treated syphilitic mothers, only 4 bore infants with signs of syphilis. He states that more and more the opinion is gaining ground that

for the prevention of congenital syphilis, energetic antisyphilitic treatment is more important during pregnancy than before conception. Ahman[32] states that of 50 syphilitic women treated energetically during pregnancy with arsphenamin and mercury, only 7 or 14 per cent. bore children with signs of syphilis; two of these were infected during the seventh month of pregnancy but received insufficient treatment.

Regarding the kind of treatment to employ, practically all physicians are in agreement on the use of arsphenamin or one of its substitutes in place of mercury. Meyer[33] quotes Sauvage's statement that only 25.46 per cent. living children were born to 217 women with evidences of recent syphilis treated systematically with mercury and iodid, and 10.18 per cent. of the living had signs of syphilis. He then states that salvarsan treatment in seventeen clinics resulted in the birth of 86 to 100 per cent. living children. In his own experience 97.4 per cent. were born alive, 86 per cent. were living by the tenth day and only 15.8 per cent. had a positive Wassermann reaction. Kirkpatrick[34] also states that the organic arsenicals yield best results and that treatment should be instituted as soon as possible but is worth while even in the late months of pregnancy. His method has been to give three courses of eight injections each of neoarsphenamin and of 148 syphilitic mothers so treated, 107 gave birth to apparently healthy children.

A great deal in the success of prenatal treatment depends upon how *early* in pregnancy it is given; certainly the earlier it is instituted the better are the results, probably because infection of the placenta and fetus is prevented. But in cases in which treatment is instituted later in pregnancy, say about the third to fifth months, is it possible to influence the disease in the fetus? We have no accurate information on the question of passage of mercury and the organic arsenicals from the mother to the fetus. Some believe that while the normal placenta is impervious to these drugs that the syphilitic placenta is permeable. Judging largely on the basis of clinical results it would appear that mercury and arsphenamin or one of its substitutes, administered to the mother, reach the fetus with curative effects so that even though the fetus is infected, therapeutic results may follow the administration of antiluetic drugs to the mother.

But may antisyphilitic treatment of the mother be harmful? This important question requires consideration from the standpoint of toxicity of the drugs for mother and child and the possibility of treatment of the mother exciting latent infection in the nature of Herxheimer reactions with added danger of infection of the child. Insofar as toxicity of the drugs is concerned, it would appear that both mercury and the organic arsenicals are well borne by both mother and child. But dosage should be conservative, bearing in mind that the kidneys and liver of the mother are already called upon for extra elimination. Fortunately it would appear, and especially from Williams investigations, that excellent results are to be observed with what may be designated as mild and very conservative treatment because the action of the drugs are probably aided by an increased degree of immunological resistance as a result of the pregnant state. Moderate doses of arsphenamin and neoarsphenamin are well borne and apparently do not promote either abortion or hemorrhage, although I believe preference is to be given to neoarsphenamin and sulpharsphenamin, because these are less vasculotoxic and least likely to produce toxic reactions which may result in abortion or miscarriage and especially since these accidents are always threatened in syphilitic pregnancies.

As regards the possibility of Herxheimer reactions, the subject can only be discussed from the theoretical standpoint. In cases of latent maternal

syphilis in which the fetus may escape infection altogether, it is possible that the administration of antiluetic drugs and especially large doses of the arsenicals by intravenous injection, may excite spirochetic activity with the production of spirochetemia and infection of the placenta and fetus, thereby defeating our very purpose and efforts. For this reason, I believe it is well to institute treatment of these cases with at least one month of mercury and iodids to be followed by the arsenicals; on the other hand, if the mother has acute active syphilis, it is a mistake to give this kind of treatment, since immediate and more energetic measures are indicated.

Fordyce and Rosen[35] have advised a course of 6 to 8 intravenous injections of arsphenamin in dose of 0.3 to 0.4 gm. or of neoarsphenamin in dose of 0.45 to 0.6 gm. at weekly intervals followed by 12 to 15 intramuscular injections of the bichlorid or salicylate of mercury in dose of 1 grain.

Author's Method of Prenatal Treatment.—My method of treatment is usually as follows:

1. If the mother's infection is latent with no evidence of syphilis other than a positive Wassermann reaction, and if treatment is instituted during the first three months of pregnancy, one month of inunctions is first given at the rate of three rubs per week of one dram of blue ointment or 85 per cent. calomel ointment. If inunctions cannot be given, the succinimid or salicylate of mercury in oil are injected intramuscularly once a week, in dose of 1 grain; if these prove too painful, potassium tartrobismuthate in oil is given, once a week, in dose of 0.2 gm. by intramuscular injection.

2. This course is followed by eight intravenous injections of neoarsphenamin in dose of 0.6 gm. once a week or eight epifascial injections of sulpharsphenamin in dose of 0.4 gm. once per week.

3. These two courses require about three months and if pregnancy has now arrived at about term treatment is continued until delivery, in the form of inunctions of mercury or injections of bismuth mercury or mercury by ingestion. On account of the necessity for avoiding gastro-intestinal disturbances and especially diarrhea, I prefer inunctions at the rate of three per week for another month or two; if these cannot be given, either mercury or bismuth by intramuscular injection may be continued at the rate of one every 7 to 10 days but not beyond twelve injections. If pregnancy is about the sixth to seventh month another course of six to eight injections of neoarsphenamin may be given followed by mercury to term.

4. If the mother's infection is early and acute the preliminary month of mercury may be omitted and treatment instituted with injections of neoarsphenamin or sulpharsphenamin in the same manner as described. This course is followed by twelve to fifteen weekly intramuscular injections of either succinimid of mercury in dose of 1 grain or 0.2 gm. potassium tartrobismuthate and after a suitable rest, the course of neoarsphenamin or sulpharsphenamin is repeated, since the indications are to give as intensive and continuous treatment as consistent with safety throughout pregnancy. As so well stated recently by Lawrence,[35a] a great deal may be done toward lowering the incidence of congenital syphilis by the proper treatment of women during pregnancy and especially in prenatal clinics. Underhill and Amatruda[35b] have shown in experiments employing pregnant rabbits and cats that arsenic may be found in small traces in the fetal tissues after the intravenous injection of neoarsphenamin into the maternal circulation and while it apparently did not increase in proportion to the number of injections given, the suggestion is made that the high efficiency of antenatal treatment of syphilis is due to the greater concentration of the spirocheticide in the placenta.

Various Methods for the Specific Treatment of Congenital Syphilis.—Needless to state, many methods have been described for the specific treatment of congenital syphilis but only those of comparatively late years including the administration of the arsenicals, would appear worthy of serious attention, since treatment with mercury and the iodids alone are known to yield inferior results.

Choice of Drugs and Dosage.—Among the organic arsenicals preference is to be given to neoarsphenamin and sulpharsphenamin, the former by intravenous injection. Children appear to stand these compounds very well and it is usually possible to make the doses as large or even slightly larger than given adults per kilogram of body weight. With experience it is frequently surprising how easily and readily intravenous injections may be given to even infants, since neoarsphenamin may be administered with a 1 or 2 c.c. syringe and a fine needle. The doses may be the same for both neoarsphenamin and sulpharsphenamin, namely, about 0.015 gm. per kilogram (2⅕ pounds) by either intravenous or intramuscular injection; arsphenamin is given in slightly smaller dose, namely, 0.010 gm. per kilogram of weight. According to age the doses may be somewhat as follows at weekly intervals:

Age	Neoarsphenamin and Sulpharsphenamin, Gm.	Arsphenamin, Gm.
Birth to 3 weeks	0.04	0.02
4 to 8 weeks	0.06	0.03
2 to 6 months	0.10	0.05
6 to 12 months	0.15	0.10
1 to 2 years	0.20	0.15
3 to 5 years	0.30	0.20
5 to 12 years	0.40	0.30

Children also bear mercury well and it is probably best given by injection; Leredde and Drouet,[36] White and Veeder,[37] Fordyce and Rosen and others have stated that inunctions are inadvisable since it is almost impossible to have them given properly over a long time by mothers; in hospital treatment, however, when inunctions may be given by trained nurses, the method is an excellent means for the administration of mercury. According to Ramsay and Groebner[38] the ordinary 50 per cent. blue ointment is to be preferred to less concentrated forms and need not be repeated more than twice weekly instead of daily. For internal administration mercury with chalk appears to be the favorite; Le Boutillier,[39] however, prefers calomel. The doses of the various mercurials may be somewhat as follows:

A. *By inunction:*

30 to 50 per cent. mercurial ointment: 15 grains twice weekly.
85 per cent. calomel ointment: 15 grains twice weekly.

B. *By intramuscular injection* (bichlorid, succinimid or salicylate in oil; mercurosal or bichlorid in water) once a week:

3 to 8 weeks: $\frac{1}{20}$ grain (0.003 gm.)
2 to 6 months: $\frac{1}{10}$ grain (0.006 gm.)
6 to 12 months: $\frac{1}{8}$ grain (0.0075 gm.)
1 to 3 years: $\frac{1}{6}$ grain (0.01 gm.)
3 to 5 years: $\frac{1}{4}$ grain (0.015 gm.)
5 to 12 years: $\frac{1}{3}$ grain (0.02 gm.)

C. *By ingestion* three times daily:

(1) Mercury with chalk: $\frac{1}{8}$ to $\frac{1}{2}$ grain. Dover's powder may be added: $\frac{1}{20}$ to $\frac{1}{12}$ grain.
(2) Bichlorid of mercury: $\frac{1}{200}$ to $\frac{1}{60}$ grain.
(3) Calomel: $\frac{1}{40}$ to $\frac{1}{10}$ grain.
(4) Potassium iodid: 1 to 5 grains.

Bismuth has been favorably reported upon by Genose and Mazzacuva,[40] Galliott,[41] Bentivoglio[42] and others by intramuscular injection once a week. I have employed potassium tartrobismuthate with success in dose of 0.004 gm. per kilogram for ten to twelve intramuscular injections. For a 6 pound infant this would be about 0.01 gm. or one twentieth the dose ordinarily given an adult at one time, older children receiving larger doses according to body weight.

Mixed treatment with the arsenicals, mercury and iodids is generally employed, very much as in acquired syphilis of adults. Kachel[43] has advocated intr avenous injections of mixtures of neoarsphenamin and mercury (bichlorid, cyanid or novasurol) as described in Chapter LXVII; Engel[44] warns against too intensive treatment of acute syphilitic infants in order to avoid overflooding the tissues with the products of destroyed spirochetes. Indeed, the literature is very full of suggestions, a good review of the subject of congenital syphilis in general having been recently published by White,[45] but it will probably suffice to give here a few of the better known methods developed within the past few years.

One of the best known of the modern methods is that employed by Fordyce and Rosen[46] in the Vanderbilt Clinic of New York. In their method, neoarsphenamin and bichlorid of mercury are given intramuscularly. If the infant is very much under weight with a poor musculature, mercury alone is given at weekly or bi-weekly intervals until there is an improvement in the general condition, after which the injections of neoarsphenamin are begun.

The bichlorid is put up in palmatin in individual collapsible ampules in doses of from $\frac{1}{10}$ to $\frac{1}{8}$ grain or larger for older children. "The object in giving a soluble mercury in oil is to favor slow absorption of the drug. In this form it requires about three or four days for absorption. The palmatin, which is in colloidal state, is semi-solid at room temperature and liquefies at 110°F. When ready for use, the syringe being still warm after its removal from the sterilizer, the contents of the ampule are expressed into the barrel, all the air removed, and if the oil has not liquefied from its contact with the hot syringe, the latter with the drug may be immersed for a minute in hot water.

"An ordinary mercury needle of from 19 to 20 gauge, cut down to from one-half to 1 inch in length, is used. After the buttock has been sterilized with iodin, the injection is given into the muscle about 1 inch from the intergluteal fold near its upper angle. The chief pain is that induced by the prick of the needle, as the children as a rule stop crying as soon as the treatment is completed."

Of 128 treated patients with active syphilis treated by this method,[47] 55 had received two courses or more of neoarsphenamin and mercury intramuscularly; of these 30 patients, or slightly more than 53 per cent., became negative clinically and serologically, the observation period now extending over two years in some instances. The remaining 73 cases consisted of two groups—one made up of younger infants, of whom 22 or 30 per cent., became negative with less than two courses of injections given regularly, and the other made up of older children who had received less than two courses of treatment scattered over irregular intervals and who had remained positive.

Jeans[48] has employed a somewhat similar method and with it White and Veeder report that, of a group of 308 cases whose end results are known, 67 or 22 per cent. were apparently cured or recovered; 108 or 35 per cent. were improved; 55 or 17 per cent. unimproved and 78 or 25 per cent. died.

Gertrude Meyer[49] employs a method consisting of 12 calomel and 12 neoarsphenamin injections over a period of 12 weeks; DeBuys[50] and Schuss-

ler[51] have described methods of mixed treatment with neoarsphenamin and mercury. Adams[52] has employed injections of galyl and gray oil while Crawford[53] and Boone and Weech[54] have employed sulpharsenol (sulpharsphenamin). The latter employed intramuscular injections of 0.02 gm. per kilogram of weight in courses of six at weekly intervals. The patients are then given mercury inunctions for two months in the form of a pea sized portion of one-third strength mercury ointment on a flannel abdominal binder. This course is followed by another course of sulpharsphenamin and treatment continued until three complete courses were given after the first negative Wassermann reaction, so that each child receives a minimum of at least four courses. The local and general reactions to the sulpharsphenamin were found very slight and in 55 per cent. of their patients, the Wassermann reaction became negative after one course of six treatments.

Specific Treatment of Congenital Syphilis after Birth through the Mother's Milk.—As stated in Chapter XLIII, the organic arsenicals, like arsphenamin and neoarsphenamin, are to be found in the milk of many nursing mothers receiving intravenous injections of these compounds. I have seen several cases of newborn syphilitic infants greatly benefited through the milk of mothers under active treatment with these compounds. The administration of mercury to mothers is not followed by as good results. Most writers, however, state that this is not a good or acceptable manner for the treatment of congenital syphilis, but when the arsenicals cannot be given to the child, I believe it is well to give them to the mother if she is nursing her infant, and particularly since she is in need of treatment anyhow if her condition permits.

Author's Method for the Specific Treatment of Acute Congenital Syphilis. I have found it serviceable to divide cases of congenital syphilis into two main groups from the standpoint of specific therapy, namely, (*a*) those presenting evidences of syphilis at birth or soon thereafter and embracing the acute symptomatic and acute asymptomatic types previously described and (*b*) those developing signs and symptoms of syphilis later in life, as after the first year.

The treatment of the first group is, of course, the most difficult because the infection is heavier and more virulent and the child greatly handicapped by poor development, poor musculature and nutrition and a great predisposition to gastro-intestinal disturbances. When they are breast fed by the mother the prognosis is much better; when artificially fed the problem is a difficult one requiring the co-operation of the experienced pediatrician and very careful nursing. Insofar as specific treatment alone is concerned, my usual method is as follows:

1. For the first two months a weekly intramuscular injection of 0.04 to 0.06 gm. of neoarsphenamin or sulpharsphenamin dissolved in 1 to 2 c.c. of sterile distilled water. At the same time two weekly inunctions of *unguentum hydragyrum dil.* (30 per cent.) are given in dose of 15 grains (about 1 gram) gently rubbed into the skin of the abdomen for at least five minutes followed by a flannel binder, which is changed once a week. At the same time the mother should be receiving treatment which may aid the nursing infant in addition to the effects from its own injections.

2. This is followed by a weekly intramuscular injection of bichlorid, succinimid or salicylate of mercury in dose of $\frac{1}{20}$ to $\frac{1}{10}$th grain for three months (12 injections).

3. A rest of one month may now follow or during this period mercury with chalk, with or without Dover's powder, may be given in dose of $\frac{1}{8}$ to $\frac{1}{4}$ grain two or three times a day by ingestion.

4. This is followed by eight more weekly intramuscular injections of neoarsphenamin or sulpharsphenamin without inunctions.

5. This is followed by twelve intramuscular injections of mercury at weekly intervals or six of mercury alternating with six of potassium tartrobismuthate in dose of 0.01 to 0.06 gm. (1/6th to 1 grain) and another month of mercury by mouth.

These courses cover a period of one year and represent the minimum of treatment for any case regardless of serological or clinical results. As a general rule additional treatment is required, and, if so, may be comprised of three of the following courses in the second year and two in the third year: 4 weekly intravenous or intramuscular injections of neoarsphenamin or intramuscular injections of sulpharsphenamin, in dose of 0.2 gm. followed by 8 weekly intramuscular injections of mercury or bismuth; at the same time potassium iodid is given by ingestion in dose of 1 or 2 grains three times a day. Each course requires therefore, about three months and may be repeated with suitable rest periods until satisfactory clinical and serological results are obtained.

Author's Method for the Specific Treatment of Late Congenital Syphilis. Under this heading I refer to cases of congenital syphilis in whom specific treatment is first undertaken after the first year of age and usually between the third and twelfth years, when interstitial keratitis, mental disturbances and other signs and symptoms of syphilis may be first detected along with a positive blood Wassermann reaction. The method is essentially similar to the preceding except that intravenous injections of neoarsphenamin are more readily possible and inunctions of mercury are more satisfactorily administered. For children over twelve years of age, the methods described in preceding chapters for the treatment of late acquired syphilis of adults are applicable; of course, with reduced doses according to age and body weight. This also applies to the matter of intraspinal medication which may be required for children over twelve years but scarcely ever before this time.

1. Treatment is usually begun with three weekly inunctions of mercurial ointment (50 per cent.) or 85 per cent. calomel ointment in dose of 1/3 to 1/2 dram (1 to 3 grams) for a period of one month (12 rubs). At the same time potassium iodid is given by ingestion in daily dose of 4 to 10 grains.

2. This is followed by twelve weekly intravenous injections of neoarsphenamin in dose of 0.2 to 0.3 gm. or twelve weekly intramuscular injections of sulpharsphenamin in dose of 0.2 gm. Potassium iodid is not usually given.

3. This is followed by mercury or bismuth for a period of three months in the form of either (*a*) three weekly inunctions; or (*b*) weekly intramuscular injections of bichlorid, succinimid or salicylate of mercury in dose of 1/6 to 1/4 grain; or (*c*) weekly intramuscular injections of potassium tartrobismuthate in dose of 0.05 gm. (1 grain) or (*d*) alternate intramuscular injections of mercury and bismuth. Potassium iodid is given at the same time in a daily dose of 5 to 20 grains by ingestion (usually 4 grains three times a day).

4. This is followed by a rest of two months without specific medication or during this time mercury with chalk or the protiodid of mercury may be administered. A blood Wassermann test is now made.

Throughout the treatment the urine is examined every 2 to 4 weeks and a careful watch maintained for evidences of toxicity or overdosage of the drugs. Regardless of serological or clinical results, however, treatment is continued for another nine months by repeating the courses described in paragraphs 2, 3 and 4. At the end of this time another blood Wassermann test is made and in the case of older children and particularly those showing clinical signs of neurosyphilis, it is sometimes advisable to examine the spinal fluid. In most cases some clinical or serological evidences of syphilis are still present and specific

treatment must usually be continued for several years longer. For such cases I usually advise two courses of the following per year: 6 weekly intravenous injections of neorsphenamin or 6 weekly intramuscular injections of sulpharsphenamin; or 3 injections of each by alternate injections (the usual plan). These are followed immediately by 6 weekly intramuscular injections of mercury alternating with 6 weekly injections of potassium tartrobismuthate (a total of 12 injections covering 12 weeks). If these injections cannot be given, three inunctions of mercury are given per week for the twelve weeks. At the same time potassium iodid is given by ingestion throughout the course of three months.

Not infrequently syphilitic children of school age are greatly hampered by their disease and it is to be hoped that the Weylander school-hospital plan of management and social rehabilitation will receive the earnest consideration warranted by the importance of the subject and present results.

Prognosis in Congenital Syphilis in Relation to Specific Treatment.—In the preceding pages I have briefly summarized the results being achieved at present in the treatment of congenital syphilis. Great advances have been made within the last ten years but our methods and results are still far from being satisfactory. As a general rule the results in private practice are very much better than in clinic practice because the coöperation of the mothers is so much better and only prolonged, patient treatment yields worth while results. As previously stated congenital syphilis is usually a deeply rooted infection owing to the widespread distribution of the spirochetes and it is even possible that the parasites may have a certain measure of resistance to mercury and the arsenicals in cases in which the mothers have been under treatment. As stated by Fordyce and Rosen, the prognosis depends largely upon: (1) the amount of prenatal treatment; (2) the physical condition at birth; (3) the severity of the infection, whether visceral, cutaneous or neural involvement is present; (4) the time treatment is begun; (5) the type of treatment, and (6) the toleration to treatment. To this I would add, (7) the duration of treatment.

CHAPTER LXXVIII

SPECIFIC TREATMENT OF SYPHILIS COMPLICATED BY DRUG INTOLERANCE, NEPHRITIS, TUBERCULOSIS AND OTHER DISEASES

As repeatedly stated in preceding chapters, the methods given for the specific treatment of early and late syphilis are in the nature of suggestions only, subject to modification as demanded by individual cases. But I believe they are applicable to the majority of cases, although some conditions like natural or acquired intolerance for our chief antisyphilitic drugs, tuberculosis of the lungs, nephritis, etc., may demand important consideration and complicate any plan for the specific treatment of syphilis. It is my purpose to consider some of these conditions in the present chapter.

Specific Treatment of Syphilitic Individuals Intolerant of the Arsenicals and Mercury.—I use the word *intolerance* to include two classes, namely, those who possess a natural or acquired allergic hypersensitiveness to these drugs and those who bear them well at first and for long periods of time but who gradually become hypersusceptible as a result of accumulative toxic effects. The two conditions are usually separate entities but sometimes sharp lines of differentiation cannot be drawn, although *intolerance* expresses the clinical result in either case.

Fortunately allergic hypersensitiveness to arsphenamin and its substitutes and mercury are quite rare, that is, the type of case who cannot tolerate the drugs at all in therapeutic amounts. This subject is considered with more detail in Chapters XLVII and LI; up to the present time, I have not

encountered anyone with an intolerance for bismuth, nor have I met with individuals who were intolerant for both arsenic and mercury at the same time. Furthermore, intolerance for a drug may be largely a matter of method of administration; this is especially true of mercury which may be poorly borne in one form or by a certain method and route of administration while satisfactorily tolerated in another form or route of administration.

But in exceptional cases of syphilis and especially of late neurosyphilis, a peculiar intolerance may be manifested for arsphenamin and neoarsphenamin administered by intravenous injection in that violent immediate and early reactions or such late accidents as dermatitis, preclude a series of injections of adequate amounts. It is highly probably that sulpharsphenamin by intramuscular injection may be better tolerated in such cases because of the slower absorption, but this compound has not been in use long enough to warrant a definite statement at the present time, except to mention that Stokes and Behny have employed it in cases who developed toxic reactions to arsphenamin without toxic effects. In other words, an intolerance may be present for a particular compound like arsphenamin while neoarsphenamin is well borne; or for neoarsphenamin when sulpharsphenamin is well borne, etc.

Fortunately, intolerance for the organic arsenicals is quite rare in early syphilis and it is in these cases that intensive arsenical therapy is mostly required. As previously stated it is unwise to give less than 0.1 gm. of these compounds to adult patients with early syphilis even at close intervals since animal experiments have shown that in acute syphilis such small doses may stimulate rather than destroy spirochetes, although in chronic syphilis and especially chronic cardio-vascular syphilis, small doses over long periods of time may constitute a valuable method of treatment.

I have, however, treated cases of early syphilis with 0.1 gm. doses of arsphenamin and neoarsphenamin by intravenous injection every day for the first five days, followed by two to three injections per week for a total of twenty-five injections as a course, followed by mercury, etc., as outlined in Chapter LXXII. This dose was tolerated with occasional attacks of nausea and diarrhea when 0.3 gm. and larger doses produced severe reactions. It is probable that epifascial or intramuscular injections of sulpharsphenamin, 0.1 to 0.2 gm. in each buttock every five days, may be given to cases of this kind, but I have had no experience with this compound in such up to the time of this writing and would refuse to use it altogether in cases of post arsenical dermatittis.

In cases of extreme arsenic hypersensitiveness it may be necessary to abandon any plan of treatment with arsphenamin and its substitutes altogether and depend upon mercury or bismuth. The latter is probably to be preferred on account of its superior spirocheticidal properties and may be substituted for the arsenicals by giving potassium tartrobismuthate, sodium and potassium tartrobismuthate, bismuth trioxid, or some other suitable compound by intramuscular injection every five to seven days in dose of 0.1 to 0.2 gm.until a total of about 2.5 gms. have been injected. Intravenous injections would be still better in early syphilis on account of more rapid effects, but are regarded as quite dangerous from the standpoint of toxicity. The injections may be followed by mercury as described, but, since both metals involve the gums and gastro-intestinal tract in a similar manner, great care must be exercised in regard to toxic reactions.

If bismuth is not given it may be well to consider intravenous injections of mercury and for this purpose flumerin in dose of 0.2 to 0.3 gm. or mercurosal in dose of 0.1 gm., every five days for six injections as a course, are worthy of consideration and to be preferred to bichlorid of mercury and other soluble mercurials. These may be followed by mercurial inunctions but great care is

required in regard to toxic reactions, especially stomatitis, and it is well to watch the kidneys carefully for evidences of irritation by frequent examinations of the urine for albumin and red blood corpuscles.

Sometimes it is possible in these cases to give an occasional small injection of neoarsphenamin even though some nausea, vomiting and looseness of the bowels may follow; if so, this practice is very desirable, as better effects are produced than in treatment alone with either mercury or bismuth.

Fournier's Chronic Intermittent Treatment of Syphilis.—Even though injections can not be given, largely because of cowardice on the part of the patient—and I have known a physician contracting genital syphilis who absolutely refused injections of the arsenicals and mercury and who died five years after infection with cerebral syphilis—it is still possible to treat by Fournier's method and Fournier apparently cured some cases of acute early syphilis. His plan was somewhat as follows, subject to variation for individual cases:

1. Four courses of mercury by mouth in the first year. Protoiodid was generally given in dose of 0.1 gm. daily. This corresponds to about 1½ grains in divided doses, like ¼ grain six times daily. Each course is of two months duration with periods of one month without specific medication.

2. During the second year, three courses are given, and two or three in the third year.

3. In the fourth year he gave three or four courses of mercury and potassium iodid each of four to six weeks duration; the average dose of potassium iodid was forty-five grains daily either along with the mercury or alternating with mercury if necessary.

4. In the fifth year three courses of mercury and potassium iodid were given, each of four to six weeks duration, and two courses in the sixth year.

Specific Treatment of Syphilis Complicated by Nephritis and Hepatitis.—The treatment of syphilis occurring in individuals with acute or chronic nephritis or disease of the liver and gall tracts, presents unusual difficulties on account of the possibility of toxic reactions from interference with elimination of the drugs. In early syphilis and, especially during the secondary stage, both acute nephritis and acute hepatitis may be caused by the *Sp. pallida* with prompt improvement of the lesions upon the institution of specific medication, as already discussed in Chapter LXXV.

In both syphilitic and non-syphilitic nephritis, I believe that it is safe to administer the arsenicals in preference to either mercury or bismuth, but arsphenamin (0.2 to 0.4 gm.) is probably better than neoarsphenamin (0.4 to 0.6 gm.) because the former is really less renotoxic. As stated in Chapter LXXV, Munk,[1] Hoffmann,[2] Audrey,[3] Stokes[4] and Cole[5] have preferred arsphenamin for the treatment of acute syphilitic nephritis and I believe it is always to be preferred in these as well as other types of presumably non-syphilitic nephritis. But it is sometimes advisable to first conduct the phenolsulphonephthalein test for elimination and to gauge doses and arrange treatment accordingly. Of course the elimination of this substance may not be a true index of the functional capacity for eliminating arsenic, mercury or bismuth, but, according to my experience, there is but little trouble and danger in treatment when the test shows a total elimination in two hours of at least two thirds the average normal return.

However, the dose of the chosen drug must be reduced below that usually employed and the intervals of injection should be at least 5 to 7 days. Treatment, therefore, is milder but more prolonged with careful watch for evidences of toxic reactions and especially various skin manifestations. If intravenous injections cannot be given, as may be the case in children, epifascial injections of sulpharsphenamin may be administered and this method is always to be

preferred in the presence of large amounts of albumin and casts in the urine because of the slower absorption throwing less burden upon the kidneys than intravenous injections. After giving courses of arsenic, it is better to follow with intramuscular injections of bismuth in dose of 0.1 gm. every 5 to 7 days than with injections of mercury, because the former is less renotoxic. If these are refused, mercury may be cautiously given by inunction, but I am absolutely opposed to intramuscular injections of the salicylate, calomel or gray oil on account of having seen several disastrous cases of explosive stomatitis from cumulative effects. If mercury is injected, it is far better to inject the soluble succinimid in almond oil in dose of 1 grain or mercurosal in dose of 0.05 (1 grain) in saline once a week. Potassium iodid is generally well borne.

In the presence of infection or other disease of the liver and gall tracts, preference is to be given intravenous injections of neoarsphenamin (0.4 to 0.6 gm.) or intramuscular injections of sulpharsphenamin, as both are less hepatotoxic than arsphenamin. It may be well in cases of this kind to apply tests for hepatic efficiency as the bilirubin content of the blood or the phenoltetrachlorphthalein test mentioned in Chapter LI. The significance of these in relation to the administration of anti-syphilitic drugs has not yet been established but I believe it may be at least stated that when the results approximate normal and usual values that we may precede with treatment more boldly than when the results indicate a severer degree of hepatic injury. I frequently apply one or both of these tests to icteric or sub-icteric individuals with syphilis, acute or chronic, before outlining the plan of therapeutic attack. But it is well under any circumstances to make the doses smaller than usual and the intervals not less than five days. Courses of either arsphenamin or sulpharsphenamin may be followed by mercury or bismuth as described, as either drug is less dangerous than in cases of severe nephritis.

Specific Treatment of Syphilis Complicated by Tuberculosis and Leprosy. Tuberculosis bears an important relation to syphilis both because the latter appears to favor infection with the tubercle bacillus and antisyphilitic drugs may activate or otherwise influence tuberculous lesions in an unfavorable manner. Ravogli[6] states that in many cases tuberculosis is associated with syphilis and that tuberculosis which was latent during good health may, in consequence of syphilitic infection, become active and destructive. Marino and Fournier,[7] and Vedder[8] also assert that syphilis predisposes to tuberculosis and Hollander and Narr,[9] in a recent review of the literature covering 6324 cases of tuberculosis, assert that 494 or 10.36 per cent. were positively syphilitic.

Owing to the effects of arsenic upon capillaries, it is well not to employ intravenous injections of arsphenamin or neoarsphenamin in the treatment of early syphilis occurring in cases of tuberculosis of the lungs with hemorrhages. Intramuscular injections of sulpharsphenamin are probably much less dangerous, but I have had no experience with the drug in such cases. If there are no hemorrhages, intravenous injections may be given, but neoarsphenamin is very much to be preferred to arsphenamin, not only because it is less vasodilating, but also because concentrated solutions may be injected with a minimum of excitement and disturbance and without raising blood pressure.

The questions frequently arise: How do mercury and neoarsphenamin act upon the organism in the presence of clinically demonstrable tuberculous foci, and how do patients having latent tuberculosis tolerate energetic treatment with these preparations? Does this treatment favor the progress of an already manifest tuberculosis, and does it arouse closed latent foci to renewed activity? In a study by Teiche,[10] syphilis alone was never found to create

a state favorable to the distribution of tuberculosis, but the tuberculosis invariably manifested itself in the course of the treatment, although not usually until after a very energetic course of treatment. In patients having primary syphilis, who were subjected to intensive treatment, the body can hardly be damaged by syphilis, as the bulk of the spirochetes are destroyed before they can do harm. Nevertheless, an existing pulmonary tuberculosis may become worse, or a latent tuberculosis become active, suggesting that the principal danger may be referable to incautious treatment, which creates favorable conditions for the distribution of the tuberculosis. When a disposition to tuberculosis is explained by an impairment of the biologic chemical adjustment of the body against the tubercle bacillus, it is readily understood that the two disturbing components such as mercury and arsenicals, may occasionally upset the complicated system of forces which still maintain the balance so that the fight is decided in favor of the tubercle bacilli. This radical chemical therapeutic procedure perhaps temporarily interferes with the production of antibodies, thereby opening a wide entrance avenue to the distribution of the tubercle bacilli. But Teiche does not mean to exaggerate the danger of combined mercury and arsphenamin treatment in patients having latent tuberculosis since many tuberculous individuals readily tolerate such combined treatments. Under no circumstances, however, should a cure of syphilis with intensive treatment be enforced at the expense of the tuberculosis. How much may be ventured depends principally upon the toleration of the specific preparations and the character of the pulmonary or other form of tuberculosis. It should always be remembered that the syphilitic infection is still accessible to later treatment, whereas tuberculosis, when it has once become progressive, has an extremely unfavorable prognosis. A series of observers, with whom Teiche is obliged to agree, regard a recent syphilitic infection as less responsible for the progressiveness of an existing tuberculosis than the institution of antisyphilitic treatment.

In less severe cases the treatment may be along the lines described above but always with smaller doses than given ordinarily and with at least five to seven day intervals. Mercury and bismuth are ordinarily well borne, but iodids should be given only with caution, although Madrid[11] states that they do not prove injurious. Hartz,[12] Elliott[13] and others state that arsphenamin or its substitutes in small doses at long intervals appear to be the drugs of choice and that mercury should be used with great care, since its deleterious effects may not be immediate, but appear after several months. Potter[14] has expressed a similar opinion.

The indications for iodids in the treatment of *acute syphilis* are only slight—indeed I believe that they can be dispensed with altogether, since syphilitic fibrosis has not occurred, and iodid tends to soften tuberculous shells of fibrous tissue and to thereby spread tuberculous infection; Hollander and Narr have ascribed the malignancy of tuberculosis in one of their syphilitic patients at least in part to the iodids, whicht hey were forced to give because of an acute nephritis preventing the administration of both neoarsphenamin and mercury.

In tuberculosis of the skin, however, arsphenamin is ordinarily well borne and indeed, may have a beneficial influence as reported by Stokes and others (Chapter VIII).

The iodids are generally regarded as contraindicated in *leprosy* by most experts in this disease, when the coexistence of syphilis demands antisyphilitic treatment. Otherwise the leper appears to bear well both the organic arsenicals and mercury although the doses and route of administration require careful supervision to meet the special conditions of individual cases.

Specific Treatment of Syphilis Complicated by Diabetes Mellitus.—As stated in Chapter LXXV, in a discussion of the specific treatment of syphilis of the pancreas, the relationship of syphilis to diabetes is not clear, although it is well substantiated that the pancreas may be infected with *Sp. pallida* with evidences of diabetes and that when syphilis and diabetes coexist, specific treatment is not generally followed by improvement of the diabetes. However, Paullin and Bowcock[15] have recently reviewed the literature covering the reports of cases of diabetes apparently due to syphilis and improving under antisyphilitic treatment, adding a case of their own of glycosuria, but not classified as one of diabetes mellitus, in which antisyphilitic treatment was followed by an apparent cure of the glycosuria.

Diabetes does not usually interfere with the usual treatment of early or late syphilis if the patient is in good nutritional state and the glycosuria under control. In the presence of severe diabetes with emaciation, etc., considerable care in specific medication is required. In my experience intramuscular injections are frequently followed by excessive local reactions, potassium tartrobismuthate in oil being better tolerated than either sulpharsphenamin or the mercurials. I believe that specific treatment should consist mainly of large doses of the iodids by ingestion and mercury by inunction; small doses of neoarsphenamin (0.4 to 0.6 gm.) may be given intravenously and if the inunctions cannot be given, potassium tartrobismuthate in dose of 0.1 to 0.2 gm. by intramuscular injection may be used as a substitute.

Specific Treatment of Syphilis Complicated by Cardiovascular Disease and Focal Infections.—In advanced cardiovascular disease with decompensation or threatened decompensation of apparently non-syphilitic origin and especially that due to mitral lesions, the organic arsenicals may be given, but for intravenous injections neoarsphenamin is very much to be preferred to arsphenamin because least likely to produce disturbances of blood pressure and the vasomotor system. It is very probable that intramuscular injections of sulpharsphenamin will prove particularly useful in these cases. Mercury is to be preferred to bismuth, partly because its diuretic effects are of aid in cases of decompensation. Of course, if syphilitic infection of the myocardium or aorta are present, and this is always quite probable, treatment may be modified as suggested on page 978 for the specific treatment of cardiovascular syphilis.

In chronic *focal infections* and especially severe gingivitis with apical abscesses and infected tonsils, due care must be exercised in view of the possibility of injections of arsphenamin and its substitutes lighting up such foci with the production of dermatitis, stomatitis and allied reactions. Neoarsphenamin is the drug of choice among the arsenicals and bismuth is to be preferred to mercury.

CHAPTER LXXIX

CRITERIA OF CURE AND THE PROGNOSIS OF SYPHILIS IN RELATION TO SPECIFIC THERAPY

The criteria of cure and the prognosis of syphilis have been already discussed from different angles in preceding chapters and especially in relation to the specific treatment of different clinical types, but it may not be amiss to attempt the presentation of a brief résumé of these subjects in view of their great importance. The task is by no means an easy one as physicians undertaking the treatment of syphilis well appreciate when an honest and sincere attempt is made to answer the never failing question: "Can I be cured?" The pathologist may be too pessimistic in his reply; the clinician, mistaking clinical and serological improvement for complete cure, may be too optimistic. The patient, frequently weighed down by worry from a feeling of moral guilt and the dread of paresis, tabes dorsalis and such consequences, may easily become a victim of the deepest pessimism with the creation of those mental or pschyic disturbances so difficult of cure and aptly designated by Collins as the "syphilitic scars of the spirit;" or, as a result of prompt eradication of obvious lesions and symptoms, hastily develope a state of excessive optimism with consequent neglect of advice regarding future treatment and observation. The physician is not infrequently to blame for either state and should endeavor to maintain a midway attitude which I believe he truly may, when equipped with a good working knowledge of the pathology and immunity of disease and the possibilities of thorough modern treatment. Altogether too frequently one encounters individuals with the late lesions of syphilis, long neglected, because of the assurance previously given by physicians that complete cure had been obtained; also patients in good health, by all criteria, in the depths of gloom and despair, because of the statement that "once syphilis always syphilis."

What Constitutes the Cure of Syphilis?—Upon first thought this question may sound foolish and unnecessary since the answer may be: when all of the spirochetes have been eradicated from the tissues. This is the only reply that the pathologist can give; but may it not be unduly exacting from the clinician's point of view? Is there such a thing as the "cure" of syphilis in the clinical sense even when we are reasonably sure that some living spirochetes still remain in the tissues? The serologist is apt to insist upon a state of permanently negative Wassermann reactions with the blood and the absence of all abnormalities in the cerebrospinal fluid. But is it possible to have a "cure" in the clinical sense with persistently positive blood Wassermann reactions and various spinal fluid changes?

So the question of the "cure" of syphilis is subject to wide variations in interpretation and must be determined in each case by thorough investigation from different angles. Some physicians are willing to base an opinion solely upon the clinical status; this is a mistake and especially since the accuracy of clinical observation and detection of syphilitic lesions is subject to even greater variation than the much abused Wassermann reaction.

Others are willing to base an opinion largely upon the results of sero-biological tests and these may lead to error, because there is a limit to their sensitiveness as well as wide variations in the data they yield according to the methods employed. If we had a test so sensitive and so specific that it could detect the very last vestiges of syphilitic infection, our search for a sign or signs of the cure of syphilis would be ended; but we do not have such and there is therefore, much room for speculation and opinion, neither of which are lacking in the literature upon the treatment of syphilis. As stated above, it is an easy matter to answer the question on what constitutes the cure of syphilis by stating, the complete eradication of all living spirochetes and the correction of the damage they have done. But how do we know, during life at least, when all spirochetes are eradicated? And is it possible to correct the damage they have done even if this is accomplished? Or should we be content to put out the fire even though unable to rebuild the house? "Cure" from the standpoint of most patients means the complete eradication of all spirochetes, complete correction of all damage and total restoration of all impaired functions; this is their hope and ideal. But the physician knows that, while these ends may be accomplished in some cases and especially in early cases of syphilis efficiently treated, the word "cure" has to be interpreted a little less exactly in the majority of cases and made to include not a few in which all further progression of the disease is stopped for the usual span of years even though the pathologist may find after death the presence of unhealed lesions apparently producing no signs or symptoms during life.

Criteria of the Cure of Syphilis from the Clinical Standpoint.—The clinical criteria of the cure of syphilis may be summarized as follows:

(1) The complete and total absence of all signs and symptoms of *progressive* visceral infection. This, of course, cannot be determined by a single examination but only by very careful physical examinations at intervals over a period of years.

(2) The improvement or regression of lesions as the result of healing. In this connection is to be remembered, however, that some damage cannot be repaired and especially injuries of the central nervous system. While we may confidently expect some improvement in most cases, yet if further progression is stopped, all is being done that may be expected. Indeed, a nerve cell or tract injured by *Sp. pallida* may continue to degenerate by reason of nutritional disturbances even after the organisms have been destroyed and the same may be true in the liver, heart and other organs. Furthermore, the very act of healing may introduce a new set of symptoms as shown by the development of ascites due to the contraction of fibrous tissues in a syphilitic liver. Likewise in the aorta or other artery, healed patches of mesarteritis with fibrosis may stretch under pressure and result in dilatation or aneurysm even though the syphilitic process itself primarily responsible for the condition has been checked or even eradicated. In syphilitic aneurysms of the aorta it is not uncommon to find that stretching is progressive when the Wassermann reaction indicates a great reduction in spirochetic activity and I have known of cases to succumb with syphilitic apoplexies when there were reasons for believing that the syphilitic processes were completely checked, as indicated by progressive reduction in the Wassermann reactions during life and the results of histo-pathological examination after death. In paradoxical cases of this kind, it is very easy indeed, to fall into the error of ascribing such progressive changes to active syphilis whereas they may be due to processes of healing leaving weak links in a chain that breaks under functional activity. I freely grant that the distinction cannot always be made clinically, but the possibility of such paradoxical results must be kept in mind.

(3) In some cases roentgenological examinations are of value as showing cessation of syphilitic changes, especially in the aorta, and they should be enlisted as additional clinical evidence of cure.

(4) Mental symptoms must not develop or, if present and due to syphilis, should not become progressively worse. This, however, is a subject that I am not able to discuss at length because a differentiation must be made between those psychic disturbances due to syphilis and those of other origin. Only a skilled psychiatrist can pass judgment upon these and especially one trained in the special psychic phenomena of syphilis. But it may be stated that if psychic changes due to organic lesions of syphilitic origin are present, that they too must show clinical improvement if "clinical cure" is claimed to have been accomplished.

It is ordinarily stated that following the treatment of early syphilis, one of the criteria of cure is freedom from all manifestation for at least a year; it is obvious that this time is too short since internal lesions may develop and easily escape detection. The period of observation must be over a number of years with occasional physical and serological examinations, although specific medication need not be given during this time.

Criteria of the Cure of Syphilis from the Sero-biological Standpoint.—The sero-biological criteria of the cure of syphilis may be summarized as follows:

(1) A persistently negative blood Wassermann reaction. A single negative reaction is of little or no significance in this relation, because if specific medication is stopped upon its appearance, positive reactions occur at later periods in many cases. As a criterion of cure, the test should be repeated every four months for at least two years and then once or twice a year thereafter for an additional several years. The technic must be as sensitive as consistent with specificity and methods lacking in sensitiveness are capable of doing more harm than good because of the mis-information and sense of false security which they yield. Is a persistently negative blood Wassermann reaction to be accepted as a good criterion of cure? May it not be negative in the presence of active lesions? My answers to these important questions may be now based upon six years of experience with my new complement fixation method, which I believe combines the maximum of sensitiveness consistent with specificity; the experiences of others may not agree with mine because the technic employed for conducting "Wassermann tests" varies so much in different laboratories and exerts such a tremendous influence upon the results in latent syphilis that falsely negative reactions may occur when the numbers and activity of the spirochetes are so reduced that sufficient "reagin" or antibody is not present in the blood serum to yield a positive reaction unless a sensitive method is employed. But falsely negative reactions are extremely rare in the presence of active lesions of syphilis. Stokes and Des Brisay report about 7 per cent. falsely negative reactions in active cases of syphilis but my experience in no way corresponds to theirs. In neurosyphilis the blood reaction may be negative when the spinal fluid shows positive reactions, but this is largely confined to asymptomatic cases. My experience teaches me that the positive complement-fixation reaction is one of the last signs of syphilis to disappear under treatment; that it is one of the first to recur if "cure" has been incomplete; that it may be a sign of spirochetic activity when there are absolutely no clinical signs or symptoms of syphilis; that a persistently positive reaction by a technically correct and acceptable method is a sure sign of syphilis, despite a condition of good general health and the begetting of apparently healthy progeny; that an individual yielding a persistently positive reaction by an acceptable method cannot be regarded as "cured" in the complete sense although he may be in the clinical sense inso-

far as symptoms are concerned; that a persistently negative reaction is not an infallible index of complete cure although, when based upon a sensitive and technically correct method, it is one of the safest and best criteria of "cure;" that the majority of individuals yielding persistently negative reactions by a sensitive method need not fear the development of late lesions and especially if this state is associated with a normal spinal fluid.

(2) A provocative Wassermann test with negative results is of additional value if conducted along the lines laid down in Chapter XLI, but as a general rule is of much less value as a criterion of cure than as an aid in diagnosis of untreated cases of latent syphilis.

(3) Persistently negative flocculation reactions and especially by Kahn's method, have much the same significance as a criterion of cure as persistently negative complement fixation reactions. In occasional cases of treated syphilis, however, the flocculation reaction may be positive when the complement fixation reaction is negative; the reverse occurs less frequently. I do not know at this time what may be the proper interpretation of these reactions, since more time and experience are required for evaluation, but I believe it is safe to assume at present that they may be an indication of continued infection and that only persistently negative reactions in both tests are acceptable as a criterion of "cure."

(4) The spinal fluid must show no increase in pressure; the cells must not be above 10 per cubic millimeter; there must be no increase in proteins or reduction in dextrose; the colloidal gold, colloidal mastic, colloidal benzoin and similar tests must yield negative reactions and the complement fixation test must yield a negative reaction with a sensitive method employing large amounts of fluid. Is one examination of the spinal fluid with such results sufficient? If made after the first six months or year of treatment, it probably is in the great majority of cases but a second examination two or three years later is advisable in order to be surer that there is no involvement of the central nervous system and this is especially true, if abnormalities were found in the first examination. Can neurosyphilis be present with a perfectly normal spinal fluid? In other words, is a normal spinal fluid a guarantee that the meninges, brain and cord are absolutely free of syphilis? I believe it is in the majority of cases, but that small vascular lesions and even very early posterior root and ganglion meningitis of incipient tabes dorsalis may escape detection and especially by one examination (much less so by repeated examinations). A negative spinal fluid examination therefore, is not an absolute criterion of freedom from syphilitic infection, but apparently, in the great majority of cases, is acceptable as an indication of freedom of infection of the central nervous system and especially when repeatedly negative.

Criteria of the Cure of Syphilis from the Pathological Standpoint.—These criteria are of course not available during life but are of great value for aiding us in a proper estimation of the clinical and sero-biological criteria of cure. They may be summarized as follows:

(1) There must be no gross lesions of syphilis in the aorta, heart, liver, meninges and brain, bones, joints, etc. However, when the treatment of syphilis was begun after the development of lesions in the tissues, a distinction should be made if possible between the fibrosis of healing and the fibrosis of syphilis. The lymph-glands, for example, may remain fibrotic apparently after all spirochetes have been removed. Fibrotic patches in the aorta, liver, etc., may be sterile; we greatly need more investigation along these lines by rabbit inoculation tests and histological examination for *Sp. pallida* to determine whether these lesions are still syphilitic or the healed or healing lesions of syphilis in the absence of *Sp. pallida*. In other words, the mere finding of a gross lesion or lesions cannot be accepted as a sign of incured syphilis unless

they are evidently progressive and inflammatory. Should we insist upon finding the spirochetes before labeling the lesions as syphilitic? Not if I may judge by the frequency with which prolonged search of large numbers of serial sections have yielded negative results in my experience. But may the lesions of syphilis be diagnosed with certainty by naked eye examination? Some may and especially the aortic lesions, but microscopical examinations are usually required before a lesion or lesions may be definitely diagnosed as syphilitic. Can the presence of syphilis in a cadaver be excluded by naked eye examination alone? By no means and this brings up the second criterion:

(2) There must be no histological evidences of syphilis in the organs. But is it possible to identify syphilitic lesions with certainty by histological tissue changes? In other words, is there a typical tissue change in syphilis? According to my experience, both questions must be answered negatively. When *Sp. pallida* is found, the answer is in the affirmative, although other spirochetes may be mistaken for *Sp. pallida* in the tissues, but are not likely to be encountered if frambesia tropica, infectious jaundice and other spirochetic infections can be excluded. I am not at all sure that the incidence of syphilis in cadavers is as high as Warthin states and great care must be exercised against the error of mistaking histological changes due to other types of tissue injury for syphilitic lesions, including those that may have been caused by mercury and the organic arsenicals employed in treatment. Upon first thought we may conclude that thorough macroscopical and microscopical examination of the tissues after death of subjects known to have had syphilis would furnish an absolute criterion of the question of cure, but such is not the case when the above and additional sources of error in both a positive and negative way are kept in mind. There is no one criterion or method for settling the question; just as the clinician and serologist may err, so may the pathologist, and the latter by no means may claim the distinction of being the final arbiter of the question.

Is Syphilis Curable?—So, with all these criteria and demands of evidence regarding the question of the cure of syphilis, we may well ask, Is the disease curable?

In the first place is syphilis curable without the use of drugs, that is, by immunological processes unaided by specific medication? Undoubtedly many untreated cases of syphilis develop long periods of clinical and serological latency approaching in these respects as good a state of general health, working capacity and efficiency as our best treated cases, but, as stated in Chapter XXXVII, there are no reasons for believing that the body defenses are capable of completely ridding the tissues of *Sp. pallida* unaided by specific medication in any more than a very small, doubtful and unknown percentage of cases. It is my opinion, therefore, that the complete and spontaneous cure of syphilis is of exceptional occurrence and that any syphilitic who deliberately refuses treatment and decides to take a "chance," is running grave risks of developing the late lesions of the disease. Negroes appear to have a better chance in this direction than whites and women of both races, who have borne children, have a much better chance than the males of both sexes, since syphilitic pregnancies appear to enhance the immunological mechanism of resistance to *Sp. pallida.* It is true that the Wassermann test may become persistently negative in untreated cases of syphilis, but this is not alone acceptable as a criterion of cure or safety and especially since many of such cases show the spinal fluid changes of asymptomatic neurosyphilis. But immunological or tissue resistance is sufficient in many cases for holding *Sp. pallida* in check and in the cases of syphilitics who have reached 55 to 60 years of age, who are in good general health and apparently symptom free because of extreme latency of infection even though the Wassermann reaction is positive, I believe it is well to depend

upon a continuation of this state to carry the individuals to the usual span of life, rather than to institute active specific medication which may disturb the latency and activate lesions beyond the means of our control, much less our ability to cure.

Is syphilis curable by specific medication? I do not hesitate to state as my opinion that many, the majority, of cases of early syphilis treated according to the modern intensive methods, are apparently cured by all the criteria applicable during life. I state "apparently" because no one is able at present to express a definite and final opinion since sufficient time has not yet elapsed for judging the results of modern therapy. But how about those cases treated by the old mercury-iodid method of Fournier, Hutchinson and others? We now know that these methods did not cure as frequently as the older syphilologists believed, since they depended entirely upon clinical criteria while we have brought to bear upon the question the much more exacting sero-biological methods. But no one can deny that many cases of syphilis were apparently cured by these older methods as judged by all of our present day criteria. In other words, I believe it may be stated that early syphilis is curable in many instances by the older methods of treatment and a much larger percentage by modern methods, if one may express a preliminary opinion of the latter by results up to the present time. On the other hand, there are some cases of syphilis apparently incurable by even the most persistent hammering with all the drugs in the therapeutic arsenal for syphilis. Virulence of strain, possibly the question of tissue affinity of the strain, natural resistance and above all, inherited or acquired predisposition to infection of the central nervous and cardiovascular systems, intolerance for drugs, persistence in treatment, etc., are factors of varying importance that influence the results in any given case.

Is chronic or late syphilis curable? I believe that many cases are to the extent of being rendered free of symptoms and serologically negative over the usual span of years, even though absolute or complete "cure" may not have been attained, as determined by the finding of microscopical evidences of the disease after death. But after all "clinical cure" is the most important consideration. In the majority of cases of late syphilis efficient treatment is at least capable of arresting the progress of the disease and relieving many of the symptoms, even though cure in the sense of complete eradication of all spirochetes may not be possible. Indeed, it may not be advisable or wise to even attempt securing the latter result if there are chances of injuring the liver, kidneys and other organs by excessive amounts of antisyphilitic drugs, or if the administration of these reduces the general health of the individual by their toxic or untoward effects.

Just as we can never be sure of the complete cure of tuberculosis, arthritis and other chronic bacterial infections, neither can we be sure of the cure of syphilis and especially chronic or late syphilis; but we can render the individual free of danger from infection to others including the progeny and bring about a state of clinical and sero-biological cure that so nearly approaches complete eradication of all spirochetes as to amount practically to the same thing. But before we are safe in pronouncing any one as "cured" the following conditions are demanded:

Clinical criteria
- (1) Complete absence of all signs and symptoms of active syphilis over a period of years although the individual may show the permanent effects of the disease after progression has ceased and healing occurred.
- (2) The regression and healing of lesions.
- (3) Roentgenological evidences of regression and healing.
- (4) Absence of syphilitic psychoses.

Sero-biological criteria	(1) A persistently negative Wassermann reaction by a sensitive method over a period of years. (2) A negative provocative Wassermann reaction. (3) Persistently negative flocculation reactions over a period of years. (4) Persistently negative spinal fluid reactions.
Pathological tissue criteria	(1) No macroscopical lesions of active syphilis although healed lesions may be present. (2) No microscopical or histological evidences of syphilis, although healed lesions may be present. (3) Absence of *Sp. pallida* in the tissues.

Relation of the Kind of Treatment to the Cure and Prognosis of Syphilis. To attain these ends it is furthermore quite surely indicated that specific treatment must be prolonged, persistent and sufficiently intensive. With the discovery of arsphenamin it was hoped that a short and royal road to cure was possible, but we now know that the syphilitic should undergo almost as long as a course of treatment and observation as advised by Fournier in the pre-arsphenamin days.

The influence of the kind of treatment or no treatment at all, upon the incidence of lesions, latency, or apparent recoveries, has been very well brought out by Stokes and Des Brisay.[1] They observed that spontaneous arrest of the disease, symptomatic and serologic, occurred in less than 1 per cent. of 208 untreated cases. Following treatment by mouth 6 per cent. were totally arrested and 10 per cent. were serologically negative on blood and spinal fluid after more intensive treatment. Among other conclusions reached by these investigators, bearing upon the present subject and with which I agree, may be mentioned the following:

"Cases treated by modern methods even though inadequate, exhibit a definitely lower proportion of cardiovascular, visceral, osseous, cutaneous and mucosal complications than untreated or mouth-treated cases.

"The proportion of serologically and symptomatically negative cases is much greater when even inadequate modern treatment is given than in untreated cases.

"Medical treatment of syphilis is absolutely necessary to reinforce the defense mechanism in the aggregate control of the disease.

"The decision not to treat a patient with demonstrable syphilis, implies reliance on his defense mechanism and should only be reached after the most thorough going appraisal of the status of that mechanism. Mere appearance of health or the result of any single test is not sufficient basis for decision."
